High intake of fructose present in table sugar and high fructose corn syrup has been correlated with the epidemics of obesity, hypertension, metabolic syndrome, and diabetes. In animals, the intake of fructose but not of glucose or starch can rapidly induce

features of the metabolic syndrome. In an experimental study, an intake of 200 g fructose per day in healthy overweight adult men caused a significant increase in systolic and diastolic BP, a rise in plasma triglycerides, a fall in high-density lipoprotein (HDL) cholesterol, and an increase in relative insulin resistance. Other studies have shown that a diet rich in fructose can increase intra-abdominal fat and cause insulin resistance, particularly in subjects who are already overweight. The pathogenesis of the hypertension may be related to the unique ability of fructose as a sugar to cause intracellular ATP depletion and uric acid generation. Allopurinol has been found to block the BP rise to fructose in both humans and rats.³⁸ These studies suggest that excessive sugar intake could have a role in the metabolic syndrome and that reduction of sugar intake could be beneficial. Interestingly, whole fruits, which also contain fructose, do not appear to cause metabolic syndrome, probably because of the lower fructose content and the presence of numerous antioxidants (such as vitamin C) that block the effect of fructose to induce insulin resistance.

In epidemiologic studies, substantial red meat intake (mean 103 g/day) is associated with a rise in systolic BP of 1.25 mm Hg.³⁹ Red meat intake has also been associated with an increased risk for diabetes. The mechanisms are unknown but may be related to the production of oxidants, inflammatory cytokines, or uric acid.

Supplementation with omega-3 fatty acids reduces the risk of myocardial infarction and sudden cardiac death,⁴⁰ but their effect on BP is small. In a recent meta-analysis, omega-3 supplementation significantly reduced diastolic BP by a mean of 1.8 mm Hg but had no effect on systolic BP, fibrinogen level, or heart rate.⁴¹ About ten portions of oily fish per week or nine or ten fish oil capsules per day are required, and this is not tolerated by most subjects because of belching and fishy taste. Concerns about the cholesterol content as well as dioxin and polychlorinated biphenyl content (environmental pollutants that have carcinogenic potential and, being fat soluble, can accumulate in the body) of some fish oil supplements also raise questions about the safety of very large doses.

Dietary Approaches to Stop Hypertension (DASH) Diet

The DASH randomized, controlled trial provided unequivocal evidence that nonpharmacologic methods can reduce BP.³² Subjects fed a diet rich in fruit and vegetables for 8 weeks had a greater reduction in systolic and diastolic BP (2.8 and 1.1 mm Hg, respectively) than did subjects on a typical American control diet. Subjects randomized to the DASH diet, rich in fruit, vegetables, and low-fat dairy products and with a reduced sugar and saturated and total fat intake (see Fig. 34.7), had an even greater reduction in both systolic and diastolic BP (5.5 and 3.0 mm Hg, respectively). The effects of the 8-week DASH diet were greatest in hypertensive African Americans, in whom the BP reduction was 13.2/6.1 mm Hg. Increased efficacy of the DASH diet in African Americans may reflect a greater response to the higher potassium, calcium, and magnesium content of the diet in subjects who have habitually low intake of these nutrients.

The follow-up DASH and low-salt diet study investigated the additional benefits of salt restriction over and above the DASH diet.⁴² Reduction of sodium intake from a high (150 mmol/day or 9 g NaCl) to either an intermediate (100 mmol/day or 6 g NaCl) or a low (65 mmol/day or 4 g NaCl) intake resulted in a stepwise reduction in BP, which was

approximately twice as great in subjects on the control than on the DASH diet (Fig. 34.8). In those following the DASH diet, the addition of salt restriction resulted in a relatively small additional decrease in BP (3.0 and 1.6 mm Hg for systolic and diastolic BP, respectively). Thus, the greatest benefits of salt restriction are seen in those with a poor diet (i.e., typical westernized high-fat, low-nutrient diet).

SMOKING

Cigarette smoking is a well-established major risk factor for cardiovascular disease, but its role in the development of hypertension is not well elucidated and not routinely included in recommendations for prevention and treatment of hypertension.¹ The relationship with hypertension may be confounded by changes in weight during and after the cessation of smoking. In a large epidemiologic study of middle-aged and older men from the United States, smoking was associated with a modest but important risk for development of hypertension; but in a study of Turkish adults, current smoking carried a borderline protective effect, whereas former smokers with abdominal obesity had a higher risk of incident hypertension.^{43,44} Nevertheless, smoking increases overall noncardiovascular and cardiovascular morbidity and mortality, and all smokers should be advised to quit.

ALCOHOL

There is a linear relationship between alcohol consumption, BP levels, and the prevalence of hypertension in populations.⁴⁵ In Japan, alcohol intake above 300 g/wk (about three drinks per day) was associated with significantly greater increases of BP during a 7-year period, and baseline BP was higher in drinkers consuming 200 g/wk, with the effects more marked in men.^{46,47} Heavy drinking is associated with increased risk of stroke, increase in BP after alcohol withdrawal, and attenuation of anti-hypertensive efficacy. Paradoxically, alcohol has a J-shaped relationship with coronary heart disease, with moderate consumption (1 to 2 drinks per day) having the lowest risk. In a large epidemiologic study, modest alcohol consumption was protective against first myocardial infarction.⁴⁸ Alcohol may increase BP through activation of the sympathetic nervous system, whereas its protective effects include increasing HDL cholesterol, lowering fibrinogen, and inhibiting platelet activation. The JNC 7 guidelines recommend limiting alcohol consumption to no more than two drinks per day (24 oz of beer, 10 oz of wine, or 3 oz of 80-proof whiskey) in most men and no more than one drink per day in women or lighter weight men (see Fig. 34.1).

CAFFEINE

Caffeine is the most widely used psychoactive substance worldwide. Caffeine stimulates the cardiovascular system through the blockade of vascular adenosine receptors.⁴⁹ In a meta-analysis of randomized, controlled studies of caffeine tablet and coffee ingestion, BP increases appeared to be greater for caffeine tablets (systolic, 4.16 mm Hg; diastolic, 2.41 mm Hg) than for coffee (systolic, 1.22 mm Hg; diastolic, 0.49 mm Hg), despite similar caffeine (total gram) intake.⁵⁰ Coffee may also increase cardiovascular risk in smokers,⁵¹ whereas paradoxically it may reduce the risk for metabolic syndrome and diabetes. The JNC 7 guidelines are silent on the issue of caffeine, but it seems reasonable to propose that modest coffee consumption is safe, at least in

Figure 34.8 Reduced sodium intake and the DASH diet. The effect on systolic blood pressure **A**, and diastolic blood pressure **B**. (Redrawn from reference 42.)

nonsmokers, but that pharmacologic ingestion of caffeine and the use of “smart drinks” (which are supplemented with caffeine) should be avoided.

PSYCHOLOGICAL STRESS

Chronic psychosocial stress is an important contributor to the development and maintenance of hypertension. Men exposed to job strain had a 10.7 mm Hg and 15.4 mm Hg higher work and home ambulatory systolic BP than did controls, respectively.⁵² The INTERHEART study showed that psychosocial stress was associated with a twofold increase in the risk of the first myocardial infarction.⁴⁸ Nevertheless, stress reduction approaches have shown either negative or heterogeneous effects on BP.⁵³ As a result, JNC 7 does not recommend stress reduction techniques for the sole management of hypertension.¹ However, evidence suggests that transcendental meditation and control of

respiration may have beneficial effects on BP as an adjunct to pharmacologic therapy.⁵⁴

ADOPTING LIFESTYLE MODIFICATIONS

Compliance with lifestyle changes has always been a concern. The Prevention of Myocardial Infarction Early Remodeling (PREMIER) trial evaluated the effects of implementing JNC 7 lifestyle recommendations and the DASH diet.⁵⁵ Adults with prehypertension or untreated stage 1 hypertension were randomly assigned to one of three groups for 6 months: advice only; JNC recommendations; and JNC recommendations plus DASH diet. At 6 months, the JNC and JNC plus DASH groups had significantly reduced BP in comparison with the advice-only group, but there was little additional benefit of adding the DASH diet to JNC recommendations. However, participants purchased their own foods in the PREMIER study, instead of being

provided with foods as in the DASH³² and DASH low-salt diet⁴² studies. Similarly, in the DASH low-salt diet study, the BP-lowering effect attributable to salt reduction was $-6.7/-3.5$ mm Hg; whereas in meta-analyses of 40 salt restriction trials in which participants prepared their own low-salt meals, this effect was only $-2.54/-1.96$ mm Hg.⁵⁶ Thus, in the outpatient setting, even highly motivated individuals usually cannot meet DASH dietary goals unless their meals are provided.

In the TOHP II study, the problems of sustainability of dietary intervention and the need for regular counseling were demonstrated.⁵⁷ The effect of adding salt restriction to weight loss appeared to offer no further decrease in BP. Assessed by urinary sodium excretion, adherence to lower dietary sodium was poor in the long term. At 36 months of follow-up, mean urinary sodium was 40.4 mmol/24 h lower than baseline in the sodium-restricted group, and only 21% achieved the target of less than 80 mmol/24 h. A higher attendance at counseling sessions was associated with a greater reduction in urinary sodium. At 36 months, a decrease of 84 mmol/day of sodium from baseline levels could be achieved only in those who attended more than 80% of the counseling sessions. In summary, the sustainability of long-term lifestyle interventions remains problematic, but it appears that regular and long-term counseling can improve adherence.

Pharmacologic Treatment of Hypertension

Bryan Williams

TODAY'S PHARMACOLOGIC TREATMENT OF HYPERTENSION IN PERSPECTIVE

Successful lifestyle interventions can delay the development of hypertension (see Chapter 34), but the majority of patients with confirmed hypertension require lifelong drug treatment, often with more than one drug. This has resulted in a billion-dollar industry, in which numerous pharmacologic agents have been introduced (Fig. 35.1). In turn, this creates complexity for clinicians in trying to decide which drugs would be the most effective option for specific patient groups. The following sections review who should receive pharmacologic treatment, what target blood pressures to attain, and how to decide on what pharmacologic agent to use.

DEFINING WHO SHOULD RECEIVE PHARMACOLOGIC TREATMENT

Definitions of Hypertension from the Perspective of Treatment

Blood pressure (BP) is normally distributed within populations, and thus “hypertension” is an arbitrarily defined, moving target with diagnostic thresholds subject to change as new evidence from clinical trials emerges. From a practical perspective, hypertension is best defined as *that level of blood pressure at which treatment to lower blood pressure results in significant clinical benefit*. This statement highlights the conundrum in defining hypertension because the risk associated with BP is a continuum and the level of pressure at which treatment results in “significant clinical benefit” for any individual will depend on the absolute cardiovascular (CV) risk.¹⁻³ This varies because some people will be more vulnerable than others to end-organ damage at a given level of pressure. Defining that vulnerability case by case remains impractical, and so differential BP targets and thresholds have emerged that group patients into categories defining their threshold BP for therapeutic intervention and optimal BP goals. In addition, specific drug classes have been given “compelling indications” and “compelling contraindications” for specific groups of patients. This has been useful in tailoring therapy from a wide range of drug classes but has sometimes been misinterpreted as indicating that the specific drug is more important than the achieved BP, which is not the case. The primary objective of therapy must always be to lower BP as effectively as possible.⁴⁻⁶

Blood Pressure Thresholds for Intervention (Office Blood Pressure)

There is substantial evidence that treating a seated “office” BP above a systolic pressure of 160 mm Hg or a diastolic pressure

above 100 mm Hg reduces strokes, myocardial infarction, heart failure, and mortality.⁴⁻¹⁰ There is also evidence that treating pressures above 140/90 mm Hg, especially in higher risk patients, is beneficial. Consequently, most guidelines define hypertension as an office BP of 140/90 mm Hg or higher.⁷⁻¹⁰ Various grades of hypertension are also specified (Fig. 35.2). Guidelines from the United States also include a category of prehypertension to highlight those with borderline hypertension.⁷ This was designed to encourage lifestyle change because the risk of progression from prehypertension to overt hypertension is very high. Furthermore, data from the Framingham Heart Study have shown that patients with a high-normal BP experience a doubling of risk of CV complications (Fig. 35.3).¹¹ Thus, prehypertension is not benign, the cardiovascular disease (CVD) risk of these people is already elevated, and they are almost certain to develop more severe hypertension without a change in lifestyle or intervention with drug therapy.

Clinical Dilemma of End-Organ Damage and a “Normal” Blood Pressure

Debate exists with relation to treating people with prehypertension who already have evidence of end-organ damage (e.g., left ventricular hypertrophy [LVH] or microalbuminuria). One wonders if this is an example of the insensitivity of the defined thresholds for diagnosis of hypertension; clearly, such a patient who has developed hypertensive LVH or microalbuminuria has a BP that is causing damage but one that is considered below the usual threshold for intervention. Thus, clinical understanding of the disease process is critical to enable the optimal use of guidelines for treatment decisions. There remains considerable uncertainty in the evidence base, and clinical judgment should not and indeed cannot be replaced by guidelines.

Blood Pressure Thresholds for Intervention (Ambulatory and Home Blood Pressure Monitoring)

Diagnostic thresholds for hypertension vary according to the method of measurement. Ambulatory BP monitoring and home BP monitoring are increasingly advocated and used. When they are used to classify hypertension, the diagnostic thresholds are lower.

The diagnostic thresholds for hypertension according to different methods of measurement are summarized in Figure 35.4 (see also Chapter 32).

WHAT ARE THE BLOOD PRESSURE TREATMENT GOALS?

An area of the greatest uncertainty is identifying BP treatment goals. As suggested before, the optimal goal of treatment is likely

The Development of Therapeutic Strategies for Hypertension	
Year	Non-Drug Treatments
1920s	Strict low-sodium diet
1929	Lumbar sympathectomy
1944	Kempner rice diet
Year	Drug Treatments
1930s	Veratrum alkaloids
1940s	Thiocyanates
1948	Reserpine, phenoxybenzamine
1950	Ganglion blockers
1951	Monoamine oxidase inhibitors
1958	Thiazide diuretics (chlorthiazide)
1960s	Central α_2 receptor agonists, nondihydropyridine calcium channel blockers and β -blockers
1970s	ACE inhibitors, α_1 receptor blockers
1980s	Dihydropyridine calcium channel blockers
1990s	Angiotensin receptor blockers
2000s	Direct renin inhibitors

Figure 35.1 The development of therapeutic strategies for hypertension. ACE, angiotensin-converting enzyme.

to be patient specific, but guidelines must be generalizable to populations. This means that guidelines, in my view, should be conservative, be pragmatic, curb the zeal of specialists to advocate ever lower BP goals, and confine their recommendations to those supported by solid evidence. Herein lies a problem. Currently, there are two internationally endorsed BP targets for people with hypertension: less than 140/90 mm Hg for those with “uncomplicated hypertension” and a lower target of less than 130/80 mm Hg for those at higher risk, that is, those with diabetes, established CV or cerebrovascular disease, and chronic kidney disease (CKD).⁷⁻¹⁰ To define such goals, ideally there should be trials that have randomized different groups of patients to different BP treatment targets (i.e., “more versus less” BP control) to determine whether the more aggressive BP target is appropriate; but despite the firm consensus on BP targets outlined before, there have been no such large-scale trials targeting more versus less systolic BP lowering and only a small number of trials targeting more versus less diastolic BP lowering.^{12,13} In an attempt to obtain more data with regard to systolic BP lowering, the Cardio-Sis study¹⁴ showed that targeting treatment to a systolic BP of less than 130 mm Hg versus less than 140 mm Hg was more effective at preventing the development of electrocardiographically defined LVH and a composite CV outcome. However, this is a single, relatively small study ($N = 1111$), and more substantial data are needed to support the recommended lower (<130/80 mm Hg) BP target (Fig. 35.5). A recent analysis of the baseline and in-treatment BP levels of patients at high CVD risk in the ONTARGET trial suggests that for people with hypertension at baseline (i.e., systolic BP ≥ 140 mm Hg), the risk of major CV events and of stroke in particular was reduced with progressive BP lowering.¹⁵ However, for those with a systolic BP of 130 mm Hg or less at baseline,

there was much less evidence of benefit with further BP lowering and a signal of possible harm. The recent ACCORD trial tested the more (<120 mm Hg) versus less (<140 mm Hg) systolic BP lowering hypothesis in a high risk population with type 2 diabetes.¹⁶ The study failed to provide conclusive evidence that the more intensive BP treatment strategy reduced a composite of major cardiovascular events, although of interest, stroke rates were significantly reduced. This study looked underpowered to definitively test this hypothesis. For the moment, a BP target of below 140/90 mm Hg should be the goal for most people with hypertension, with a more conservative target of below 150/90 mm Hg for those 80 years of age or older based on recent data from the HYVET study.¹⁷ Lower BP targets may be appropriate in higher risk patients, on a case-by-case basis, depending on the patient’s ability to tolerate lower levels of treated BP, with the caveat that the evidence supporting such a strategy is limited.

GUIDE TO SELECTION OF ANTIHYPERTENSIVE AGENTS

Key Principles from Clinical Trials

Aside from the limitations of the evidence defining optimal BP treatment targets, the pharmacologic treatment of hypertension has the most impressive evidence base in medicine to guide treatment decisions. BP lowering undoubtedly reduces morbidity and mortality, but we do not know how low to go. Many large randomized controlled trials have compared different classes of active treatments with placebo and different treatment strategies with each other (see references 4 to 6 for overviews). Figure 35.6 summarizes a recent systematic review and analysis conducted for the National Institute for Health and Clinical Excellence (NICE) hypertension guideline development group in the United Kingdom,¹⁰ which compared and ranked the effectiveness of different classes of BP-lowering medication with regard to major CV events. The differences between the various drug classes on clinical outcomes are primarily driven by differences in the quality of BP control. Analysis of these trials has provided some important guiding principles with regard to treatment strategies for hypertension:

1. Effective BP lowering is overwhelmingly important in reducing the risk of major CV events in people with hypertension. Thus, the first priority in treatment is to control BP.
2. Early studies focused primarily on diastolic BP as the treatment target, but systolic BP is invariably more difficult to control and more closely linked to CV outcomes and should now be the main focus of treatment.
3. Monotherapy is rarely sufficient to control BP, and many patients will require more than one drug as part of their treatment strategy.
4. The response to any class of BP-lowering medication is heterogeneous, that is, some patients will respond better than others.
5. Some trials have indicated that certain comorbidities (e.g., diabetes) and target organ damage (e.g., LVH, CKD) provide compelling indications for inclusion of specific classes of drug therapy in the treatment regimen, but this consideration should not override the importance of BP control *per se*.
6. There are inadequate clinical outcome data for treatment studies of younger patients. Most studies, especially the

Figure 35.2 Classification of hypertension according to current hypertension guidelines.

Hypertension grades or stages replace the older terminology of mild, moderate, and severe. DBP, diastolic blood pressure; SBP, systolic blood pressure. Drug abbreviations: ACE, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BB, β -blocker; CCB, calcium channel blocker. *Treatment determined by highest blood pressure (BP) category. †Initial combined therapy should be used cautiously in those at risk for orthostatic hypotension. ‡Treat patients with chronic kidney disease (CKD) or diabetes to BP goal of less than 130/80 mm Hg.

Classification of Hypertension according to Current Hypertension Guidelines					
European Society of Hypertension Classification of Hypertension (circa 2007)					
Category		Systolic (mm Hg)		Diastolic (mm Hg)	
Optimal		<120	and	<80	
Normal		120–129	and/or	80–84	
High–normal		130–139	and/or	85–89	
Grade 1 hypertension		140–159	and/or	90–99	
Grade 2 hypertension		160–179	and/or	100–109	
Grade 3 hypertension		≥180	and/or	≥110	
Isolated systolic hypertension		≥140	and	<90	
JNC 7 Classification of Hypertension (circa 2003)					
BP Category	SBP* (mm Hg)	DBP* (mm Hg)	Lifestyle Modification	Initial Drug Therapy	
				Without Compelling Indications	With Compelling Indications
Normal	<120	and <80	Encourage	No antihypertensive drug indicated	Drug(s) for compelling indications [‡]
Prehypertension	120–139	or 80–89	Yes		
Stage 1 hypertension	140–159	or 90–99	Yes	Thiazide-type diuretics for most. May consider ACE inhibitor, ARB, BB, CCB, or combination	Drug(s) for the compelling indications [‡] Other anti-hypertensive drugs (diuretics, ACE inhibitor, ARB, BB, CCB) as needed
Stage 2 hypertension	≥160	or ≥100	Yes	Two-drug combination for most [†] (usually thiazide-type diuretic and ACE inhibitor or ARB or BB or CCB)	

more recent, have been conducted in patients older than 55 years and typically with a mean age of more than 65 years.

- On average, lowering of BP by 20/10 mm Hg will reduce the risk of major CV events by half.
- The reduction in stroke risk appears to follow the predicted reduction in risk based on the epidemiologic association between stroke and BP.
- There appears to be a shortfall in the reduction in risk of ischemic heart disease with BP lowering compared with epidemiologic predictions, which is best addressed by attention to concomitant risk factors.
- Importantly, the risk reduction associated with BP lowering appears to be continuous across a wide range of BPs; thus, the absolute benefit from treatment is greatest in those with the highest absolute CVD risk. This provides the rationale for advocating the use of

complementary strategies to reduce CVD risk (e.g., statins and antiplatelet therapy in those with established vascular disease, with target organ damage, or at high calculated CVD risk, i.e., ≥20% during 10 years).

Selection of Drug Therapy

The major classes of BP-lowering therapies are summarized here. International guidelines recommend certain indications and contraindications for the use of specific classes of BP-lowering therapy in specific clinical situations, and these are detailed in [Figures 35.7 and 35.8](#). These lists are not comprehensive and are subject to change as new evidence emerges. The more common adverse effects associated with the major classes of BP-lowering drug therapies are shown in [Figure 35.9](#). The sites of mechanism of action of the various classes of BP-lowering drugs discussed are shown in [Figure 35.10](#).

Figure 35.3 High-normal blood pressure (BP) and the risk of cardiovascular disease (CVD). Cumulative incidence of CV events in women **A**, and men **B**, without hypertension, according to BP category at the baseline examination, showing 95% confidence intervals. For this analysis, **optimal BP** was defined as systolic pressure of less than 120 mm Hg and diastolic pressure of less than 80 mm Hg; **normal BP** as systolic pressure of 120 to 129 mm Hg or diastolic pressure of 80 to 84 mm Hg; and **high-normal BP** as systolic pressure of 130 to 139 mm Hg or diastolic pressure of 85 to 89 mm Hg. (Modified from reference 11.)

Diagnostic Thresholds for Hypertension According to Different Methods of Measurement		
	Systolic BP	Diastolic BP
Office or clinic	140	90
24-hour	125–130	80
Day	130–135	85
Night	120	70
Home	130–135	85

Figure 35.4 Diagnostic thresholds for hypertension according to different methods of measurement. SBP, systolic blood pressure (in mm Hg); DBP, diastolic blood pressure (in mm Hg); 24-hour, day, and night refer to average blood pressures in those time periods recorded by ambulatory blood pressure monitoring; home refers to an average of 7 days of seated blood pressure monitoring at home, usually twice per day (i.e., an average of ~14 readings).

Thiazide-Type Diuretics

Thiazide-type diuretics were the first major class of drug used to treat hypertension on a large scale and remain a major therapeutic option for the treatment of primary hypertension. They are referred to here as thiazide-type diuretics because these drugs do not have a common structure. Commonly used examples are chlorthalidone, hydrochlorothiazide, indapamide, and bendroflumethiazide. They all act primarily by inhibiting the Na^+Cl^- cotransporter in the distal tubule of the kidney, promoting sodium excretion, which is integral to their antihypertensive effect. The early changes in salt and water balance are often accompanied by counteractivation of several vasoconstrictor mechanisms, including the renin-angiotensin-aldosterone system, which may transiently raise peripheral vascular resistance and attenuate BP lowering. Subsequently, a gradual reduction in

peripheral vascular resistance and a new steady state of reduced total body sodium and BP are established, usually after about 2 months of treatment.

The sustained actions of thiazide-type diuretics on the kidney make them preferable to loop diuretics for the control of BP. Although loop diuretics are more potent with regard to promoting acute sodium and water loss, they are shorter acting, and there is usually compensatory sodium retention during the latter part of the dosing interval, thereby reducing their BP-lowering efficacy. Loop diuretics have no place in the routine management of primary hypertension in patients with a well-preserved glomerular filtration rate (GFR). However, thiazide-type diuretics lose efficacy in patients with a GFR below 30 mL/min. In such patients, loop diuretics are often required for effective BP lowering, especially when there is clinical evidence of sodium and water retention.

The main adverse effects of thiazide-type diuretics are hypokalemia, hyponatremia (less commonly), impaired glucose tolerance, and small increments in blood levels of low-density lipoprotein (LDL) cholesterol and triglycerides. Thiazide-type diuretics also elevate serum uric acid levels and should be avoided in patients predisposed to gout and also in those receiving lithium because of a high risk of lithium toxicity. Lithium is reabsorbed like sodium through the proximal tubule, and thus distal sodium loss due to thiazides can promote proximal reabsorption of sodium and lithium; as lithium has a narrow therapeutic window, this can lead to lithium toxicity. An incidental advantage of thiazide-type diuretics may be reduction in osteoporosis as a result of calcium retention.

There has been a trend during recent years to reduce the recommended dose of thiazide-type diuretics to minimize their adverse metabolic effects. The dose-response to thiazide-type diuretics is flat (unlike the adverse effect profile), and this has been used to justify the low-dose strategy. However, some patients respond well to higher doses of thiazide-type diuretics, which they tolerate. Moreover, when thiazides are combined with drugs that block the RAS (e.g., angiotensin-converting

Figure 35.5 Analysis of achieved blood pressure (BP) levels and clinical outcomes in various clinical trials of patients with uncomplicated hypertension A, and elderly hypertensives B. The abbreviations on the base axis refer to the trials for the source data. Open rectangles show less active BP lowering; solid rectangles show more active BP lowering. The achieved systolic BP values are shown; orange rectangles, no significant benefit of more active treatment; blue, significant benefit of more active treatment on major cardiovascular outcomes; purple bar, significant benefit limited to some secondary outcomes. Numbers refer to achieved mean systolic BP for less active versus more active treatment for each study. The dotted line shows the currently recommended systolic BP treatment target. Details are available from the source text. (Modified from reference 13.)

Relative Risk and Benefit of Drugs Used to Treat Hypertension				
Outcome	Thiazide-Type Diuretics (D)	Calcium-Channel Blockers (C)	Beta-Blockers (B)	ACE Inhibitor/ARB (A)
Unstable angina	0.893	0.881	0.984	0.970
MI	0.780	0.796	0.855	0.816
Diabetes	0.985	0.808	1.137	0.720
Stroke	0.690	0.656	0.851	0.731
Heart failure	0.530	0.731	0.761	0.642
Death	0.910	0.883	0.939	0.902

Figure 35.6 Relative risk and benefit of drugs used to treat hypertension. The figure shows effectiveness of drugs: 1.0 = no benefit or harm; <1.0 = benefit; >1 = potential harmful effect. Modified from a meta-analysis of major BP-lowering trials conducted for the NICE hypertension guideline development group, 2006. Note that angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARB) were grouped as a single class for the purposes of this analysis. MI, myocardial infarction. (Modified from data in <http://www.nice.org.uk/CG034guidance>.)

enzyme [ACE] inhibitors or angiotensin receptor blockers [ARBs]), the dose-response is steeper, and higher doses (e.g., hydrochlorothiazide 25 to 50 mg or chlorthalidone 25 mg) may be especially effective in patients with more resistant hypertension.

Potassium-Retaining Diuretics (e.g., Spironolactone, Amiloride, Eplerenone) Spironolactone is an aldosterone receptor antagonist that acts in the renal distal tubule and collecting ducts, decreasing the reabsorption of sodium and water and decreasing

the excretion of potassium. The main action of spironolactone is to decrease the tubular expression of epithelial sodium channel (ENaC) and renal outer medullary K (ROMK) channels, and thus it has a relatively slow onset and offset of action. Because its main site of action is on sodium and water handling in distal tubule and collecting ducts, it is a relatively weak diuretic. Nevertheless, it is effective as a BP-lowering agent but currently rarely used for the routine treatment of hypertension. Spironolactone has the advantage over thiazide-type diuretics that it does not cause hypokalemia or hyperuricemia, and it does not impair

Compelling and Possible Contraindications to Specific Classes of Blood Pressure-Lowering Therapies

	Compelling	Possible
Thiazide diuretics	Gout	Metabolic syndrome Glucose intolerance Pregnancy
β -blockers	Asthma A-V block (grade 2 or 3)	Peripheral artery disease Metabolic syndrome Glucose intolerance Athletes and physically active patients Chronic obstructive pulmonary disease
Calcium antagonists (dihydropyridines)		Tachyarrhythmias Heart failure
Calcium antagonists (verapamil, diltiazem)	A-V block (grade 2 or 3) Heart failure	
ACE inhibitors	Pregnancy Angioneurotic edema Hyperkalemia Bilateral renal artery stenosis	
ARBs	Pregnancy Hyperkalemia Bilateral renal artery stenosis	
Diuretics (antialdosterone)	Renal failure Hyperkalemia	
DRIs	Pregnancy Hyperkalemia Bilateral renal artery stenosis	

Figure 35.8 Compelling and possible contraindications to specific classes of blood pressure (BP) lowering therapies. A-V, atrioventricular; ACE, angiotensin-converting enzyme; ARBs, angiotensin receptor blockers; DRIs, direct renin inhibitors.

Common Side Effects Associated with Various Classes of Antihypertensive Drugs

Drug Class	Side Effects
ACE inhibitors	Cough, hyperkalemia
ARBs	Much less frequent hyperkalemia compared to ACE inhibitors
CCBs DHPCCB Non-DHPCCB	Pedal edema, headache Constipation (verapamil), headache (diltiazem)
Diuretics	Frequent urination, hyperglycemia, hyperlipidemia, hyperuricemia, sexual dysfunction
Central α -agonists	Sedation, dry mouth, rebound hypertension, sexual dysfunction
α -Blockers	Pedal edema, orthostatic hypotension, dizziness
β -Blockers	Fatigue, bronchospasm, hyperglycemia, sexual dysfunction
[K ⁺] Channel openers	Hypertrichosis (minoxidil); lupus-like reactions, pedal edema (hydralazine)

glucose tolerance. However, spironolactone has antiandrogen activity by binding to the androgen receptor and preventing it from interacting with dihydrotestosterone. Consequently, it can cause nipple tenderness and gynecomastia in some patients, which is dose dependent and can limit its use. Another concern with potassium-sparing diuretics, in general, is the risk of hyperkalemia in people with substantially reduced GFR (see later discussion).

Eplerenone is more selective for the aldosterone receptor than spironolactone is, thereby avoiding the antiandrogen effects of spironolactone. There is very limited experience of

eplerenone for the routine management of hypertension. Empirically, milligram per milligram, eplerenone appears less potent than spironolactone. Amiloride is an antagonist of the ENaC in the distal convoluted tubules and collecting ducts of the kidney, decreasing sodium and water reabsorption and promoting potassium excretion. Previously, amiloride was a popular treatment of primary hypertension, when, like spironolactone, it was often used in combination with thiazide-type diuretics. It is less used today even though it shares the advantage of spironolactone over thiazide-type diuretics of not causing hypokalemia, hyperuricemia, or impaired glucose tolerance.

The reason for the decline in popularity of potassium-sparing diuretics for the initial treatment of primary hypertension is not clear; it may reflect the emergence of ACE inhibitors or ARBs. These RAAS blockers are increasingly used for the routine management of hypertension, and there is an increased risk of hyperkalemia when they are combined with spironolactone or amiloride, especially in patients with renal impairment. Spironolactone and amiloride are increasingly used as additional diuretic therapy in patients as part of a multidrug strategy for the treatment of resistant hypertension.^{18–20}

β-Adrenoceptor Blocking Drugs (β-Blockers)

β-Blockers reduce BP and CV events in patients with hypertension. Most β-blockers, with the exception of those with strong intrinsic sympathomimetic activity, reduce cardiac output by their negative chronotropic and inotropic effects. As with diuretics, short-term hemodynamic responses can be offset by counteractivation of vasoconstrictor mechanisms, which may limit initial BP lowering. Longer term reduction in arterial pressure during days occurs because of restoration of vascular resistance to pretreatment levels. Partial blockade of renin release from the kidney may contribute to the later hemodynamic response.

β-Blockers differ in their duration of action, selectivity for β₁ receptors, lipophilicity, and partial agonist activity. Side effects include lethargy, aches in the limbs on exercise, impaired concentration and memory, aggravation of depression and psoriasis, erectile dysfunction, vivid dreams, and exacerbation of symptoms of peripheral vascular disease and Raynaud's syndrome. They are contraindicated in asthma and can cause adverse metabolic effects, including impaired glucose tolerance and worsening of

dyslipidemia, notably reduced high-density lipoprotein (HDL) cholesterol and raised triglyceride levels. There is accumulating evidence that β -blockers increase the likelihood of new-onset diabetes, particularly in combination with thiazide-type diuretics.^{21,22} Moreover, recent meta-analyses suggest that there is a shortfall in CV protection with β -blocker-based treatment of hypertension (especially in stroke reduction) compared with treatment with other major drug classes (see Fig. 35.6).^{10,23-25} As a consequence, the recent U.K. guidelines suggested that β -blockers are no longer preferred as an initial therapy for routine hypertension and should be used only when there is a compelling indication other than BP control (e.g., in patients with hypertension and angina or chronic heart failure).¹⁰ One caveat is in younger women of childbearing potential, in whom β -blockers are often effective at lowering BP, perhaps because of higher renin levels in younger people, and are safer than ACE inhibitors or ARBs in those anticipating pregnancy.

Calcium Channel Blockers

Calcium channel blockers (CCBs) are effective at reducing BP and have an extensive evidence base supporting their use for the treatment of hypertension.^{4,6} In addition to their BP-lowering properties, they are also effective antianginal agents. They appear to be metabolically neutral with regard to glucose tolerance. An interesting aspect of the BP response to CCBs is that it is largely determined by the magnitude of BP elevation, perhaps more so than with other drugs. Thus, those with higher baseline BP levels experience greater BP lowering with CCBs, whereas those with only modest elevations of BP experience much smaller falls in BP.

There are two main groups of CCBs, the dihydropyridines (e.g., amlodipine, nifedipine) and the nondihydropyridines (e.g., diltiazem, verapamil). The dihydropyridine CCBs act mainly by inducing relaxation of arterial smooth muscle by blocking L-type calcium channels, thereby inducing peripheral vascular relaxation with a fall in vascular resistance and arterial pressure. Nondihydropyridine CCBs block calcium channels in cardiac muscle and reduce cardiac output. Verapamil has an additional antiarrhythmic action through its effects on the atrioventricular node.

The earlier formulations of some dihydropyridine CCBs, such as capsular nifedipine, had a rapid onset and short duration of action, with unpredictable effects on BP. These responses were often accompanied by reflex sympathetic stimulation and tachycardia. The shorter acting oral preparations of CCBs have no place in the routine management of hypertension. More modern, longer acting formulations of dihydropyridine CCBs produce more predictable responses.

Side effects of dihydropyridine CCBs include dose-dependent peripheral edema, which is not due to fluid retention but results from transudation of fluid from the vascular compartments into the dependent tissues because of precapillary arteriolar dilation. This edema does not respond to diuretic therapy but is alleviated by limb elevation. There is emerging evidence that this edema may also be reduced by coadministration of an ACE inhibitor or ARB because of their effects on venous capacitance. Gum hypertrophy can occur with dihydropyridine CCBs but is rarely seen with nondihydropyridine CCBs. Nondihydropyridine CCBs cause less peripheral edema but are negatively inotropic and negatively chronotropic and should therefore be avoided in patients with compromised left ventricular function and in combination with β -blockers. Verapamil use is commonly accompanied by constipation.

Blockade of the Renin-Angiotensin System

RAAS has become a popular target for drug development to treat hypertension. Inhibition of RAAS is predictably effective at lowering BP by inhibiting the various central and peripheral pressor effects of angiotensin II (Ang II). Blockade of RAAS may also lower BP by other mechanisms involving improvements in endothelial function, vagal tone, and baroreceptor function and through inhibition of the renal tubular reabsorption of sodium. In addition, inhibition of RAAS has been popularized by clinical trial evidence showing reduced morbidity and mortality in patients with heart failure, delayed progression of renal disease, and reduced CV events in patients at high CV risk with treatment strategies that involve inhibition of RAAS.⁶ Three classes of drugs are now available that directly target RAAS (Fig. 35.11): ACE inhibitors, ARBs, and a new class, the direct renin inhibitors (DRIs).²⁶

Angiotensin-Converting Enzyme Inhibitors ACE inhibitors were the first effective strategy to inhibit RAAS and have been used to treat hypertension since the late 1970s. ACE inhibitors block the conversion of Ang I to Ang II by inhibiting ACE. The resulting reduction in levels of Ang II leads to vasodilation and a fall in BP. Ang II has many additional actions that are potentially harmful to the CV system and has been implicated in the pathogenesis of structural changes in the heart, blood vessels, and kidneys in hypertension. Sharp falls in BP after the introduction of ACE inhibitors may occur when the RAS is activated, for example, in patients who are dehydrated, in heart failure, or with

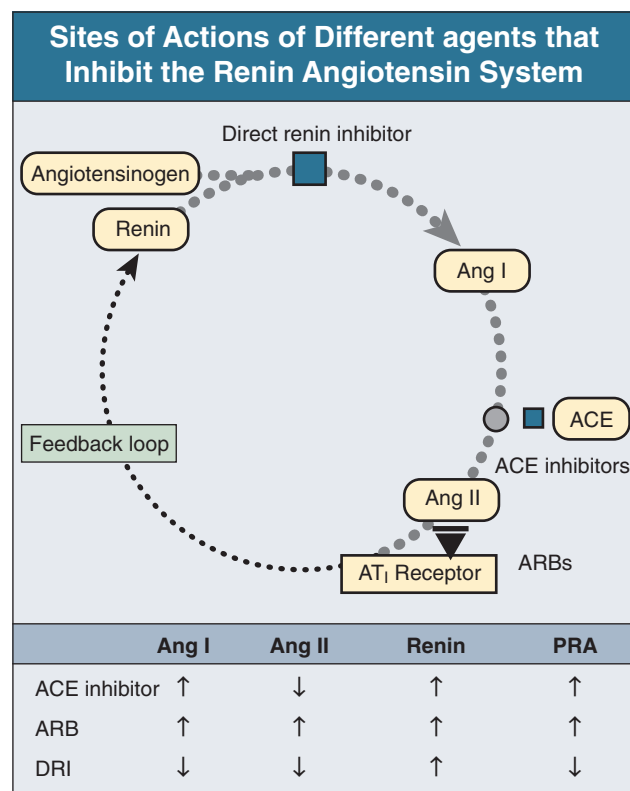

Figure 35.11 Sites of actions of different agents that inhibit the renin-angiotensin system. The resulting neurohumoral profile is also shown. ACE, angiotensin-converting enzyme; Ang, angiotensin; ARB, angiotensin receptor blocker; DRI, direct renin inhibitor; PRA, plasma renin activity.

accelerated hypertension. This is rarely a problem when therapy is initiated in uncomplicated hypertensive patients.

Side effects of ACE inhibitors include the development of a persistent dry cough in about 20% of users. This is more common in women and in people from the Far East and Pacific Rim. The cough disappears only after discontinuation of the drug. Another rare but important complication is angioedema, which occurs in ~1% and is much more common in the black population (~4%). ACE inhibitors should be avoided in women of childbearing potential because of the danger of fetal malformation. They should not be used in patients with significant bilateral renal artery disease because they may precipitate deterioration in renal function and renal failure. Careful monitoring of renal function and serum potassium concentration is also required in patients with more advanced renal impairment of any cause because of the risk of hyperkalemia.

Angiotensin Receptor Blockers In the 1990s, ARBs emerged as an alternative to ACE inhibition. ARBs are highly selective inhibitors of the Ang II type 1 receptor (AT₁). In common with ACE inhibitors, ARBs inhibit the actions of Ang II on the CV system and kidney. ARBs reduce BP as effectively as ACE inhibitors but generally have a longer duration of action than ACE inhibitors. When ACE inhibitors and ARBs have been compared “head to head,” they appear to be equally effective in reducing albuminuria and preserving GFR²⁷ as well as similar in efficacy for preventing major CV events in people with established CVD.²⁸ Because of their selectivity and specificity for the AT₁ receptor, the ARBs are well tolerated by patients, with a placebo-like adverse effect profile. Moreover, cough and angioedema are much less likely to occur with ARBs than with ACE inhibitors, and most guidelines recommend switching patients to an ARB when an ACE-induced cough occurs. Cautions and contraindications are similar to those outlined for ACE inhibitors.

Direct Renin Inhibition A third strategy recently emerged to inhibit RAAS for the treatment of hypertension: the first non-peptide, orally active DRI (aliskiren).²⁶ Aliskiren has high specificity for renin and is a potent inhibitor of plasma renin activity with a long half-life (~24 hours). Aliskiren inhibits the rate-limiting step in angiotensin production, notably the renin-dependent conversion of angiotensinogen to Ang I. The DRI appears to have BP-lowering efficacy similar to that of other means of inhibiting the renin system (i.e., ACE inhibitors, ARBs) but with less side effects than ACE inhibitors.²⁶ The contraindications to use are similar to those for ACE inhibitors, ARBs. The main factor differentiating the DRI from ACE inhibitors or ARBs is that ACE inhibitors or ARBs activate plasma renin activity, whereas the DRI inhibits plasma renin activity. Aliskiren also has a much longer duration of action than the other forms of RAAS blockade. The clinical significance of these differences in mode of action will be uncovered by an extensive ongoing clinical trial program that will ultimately define the role for DRIs in the hierarchy of treatment.

α-Adrenergic Blocking Drugs

The original members of this class (e.g., prazosin) were short-acting drugs that blocked the activation of α₁-adrenoceptors in the vasculature, leading to vasodilation. Initially, the recommended dosage was too high, and postural hypotension and syncope proved serious problems that retarded the acceptance of this class of drugs, although the use of lower doses and

the development of longer acting agents (e.g., doxazosin) have largely overcome this problem. Blockade of sphincteric receptors improves symptoms in patients with benign prostatic hypertrophy. On occasion, these same sphincteric effects can worsen symptoms of stress incontinence in women. Uniquely among antihypertensive drugs, the α₁-antagonists produce modest favorable changes in plasma lipids, with a reduction in total and LDL cholesterol and triglyceride levels and an increase in HDL cholesterol.

Centrally Acting Sympatholytic Drugs

Some of the earliest drugs developed to treat hypertension targeted the activation of the sympathetic nervous system (SNS) at various levels, including the CV regulatory nuclei in the brainstem, the peripheral autonomic ganglia, and the postganglionic sympathetic neuron. Few of these agents have any residual role to play in the modern treatment of hypertension because side effects are common and their use has been superseded by classes of drugs with a more tailored mechanism of action.

Methyldopa reduces sympathetic outflow from the brainstem. It was originally developed in the late 1950s, and it was one of the mainstays of antihypertensive therapy for many years. However, it frequently causes sedation, impaired psychomotor performance, dry mouth, and erectile dysfunction. Its unfavorable impact on quality of life caused it to be gradually replaced by more effective drugs, although it is still extensively used in the management of hypertension of pregnancy, which is now its main indication.

Clonidine is now rarely used because of its short duration of action and risks of a withdrawal syndrome, which occurs when sudden discontinuation results in a rebound rise in catecholamines with features that may resemble pheochromocytoma, such as severe hypertension, tachycardia, and sweating. This is exacerbated when patients are also receiving nonselective β-blockers such as propranolol. The syndrome is treated by readministration of the drug and then gradual discontinuation or the intravenous infusion of labetalol in an emergency. Clonidine is still used and can be effective in some patients with drug-resistant hypertension. Longer acting preparations of clonidine are being developed and may find a place in the management of resistant hypertension.

Moxonidine, a newer centrally acting agent that is an imidazoline receptor agonist, reduces sympathetic outflow and BP. It has a lower incidence of side effects and is better tolerated than other centrally acting agents. It has no clinical trial evidence to support its use as a preferred first-line agent but is used in patients with more resistant hypertension.

Direct Vasodilators

Hydralazine was previously extensively used as part of the original “stepped care” treatment regimens for hypertension. The main disadvantages were sympathetic activation and the development of a lupus-like syndrome, particularly in patients with the slow acetylator genotype. There was also the need for multiple daily dosage. Hydralazine is no longer recommended as a first-line agent for hypertension management. It is still occasionally used in severe hypertension and hypertension associated with pregnancy.

Minoxidil is a potent vasodilator, and its use is largely confined to specialist centers for the treatment of severe and resistant hypertension. This is because of its side effect profile, which is unenviable and includes stimulation of body hair growth; tachycardia and severe fluid retention reflect its potent

vasodilator action and concomitant reflex activation of the SNS. For this reason, minoxidil is usually combined with a potent loop diuretic and a β -blocker as part of a triple-therapy approach to severe hypertension. Long-term use can be associated with insidious development of peritoneal and pericardial effusions (especially in subjects with impaired renal function). These necessitate and respond to treatment withdrawal.

Treatment Strategies

Given the multiple drug classes for the treatment of hypertension, there is a need for a treatment strategy that identifies the preferred drugs for initial therapy and preferred combinations for those requiring more than monotherapy to control their BP. The use of drug therapy to lower BP should usually follow a period of observation and repeated measures of BP to ensure that there is a sustained elevation of BP that merits treatment. The duration of the observation period is inversely related to the severity of hypertension. This ranges from immediate treatment to repeated measurement during days or months.

Lifestyle interventions (discussed in Chapter 34) should be initiated during this period of observation and continued even if treatment with drug therapy is initiated. This is important because the actions of drug therapy can often be potentiated by concomitant lifestyle changes (especially body weight reduction and reduction in dietary sodium intake).²⁹ Furthermore, lifestyle changes are also important to improve the overall health and CV risk profile of the patient, beyond their impact on BP. Another key aspect of the initial assessment of patients is to identify concomitant risk factors, comorbidities, and target organ damage, all of which might influence the selection of drug therapies to improve BP control.

Initial Drug Therapy

Current practice is to initiate treatment with a single drug. Depending on the BP level at baseline, monotherapy will on average reduce systolic pressure by 7 to 13 mm Hg and diastolic pressure by 4 to 8 mm Hg; the greater reductions will generally be observed in those with the highest baseline BP.³⁰ It is emphasized that these are “average BP responses,” and there can be marked heterogeneity in response among individual patients and with different classes of drugs in individual patients. Treatment should normally commence with a low dose of the drug selected. If this is inadequate, there are a range of options:

1. If BP responds to low-dose monotherapy and is not yet controlled but is likely to be controlled with monotherapy (i.e., BP within $\sim 10/5$ mm Hg of BP goal), the dose of the initial drug should be titrated upward.
2. If the BP response to the initial low dose is inadequate and the patient's BP remains well short of the target BP, a more appropriate action is to add a second drug, either separately or as a combination tablet, because the majority will require two or more drugs to control their BP.
3. If the initial drug produced a weak response or no response at all and the patient could conceivably achieve the BP goal with monotherapy, the first drug could be discontinued and replaced with another class of antihypertensive agent.

Choice of Initial Therapy There is wide variation in the international guidelines with regard to the preferred initial therapy for primary hypertension.

The U.S. guideline, based on the recommendations of the U.S. Joint National Committee 7 (JNC 7), recommends low-

dose thiazide diuretic as initial therapy for all patients (unless contraindicated), reflecting a view that the most important driver of benefit is BP control and that the low-dose diuretic is the most cost-effective way to deliver that.⁷ It will be of interest to see whether there is deviation from this stance in the forthcoming JNC 8 guidance due to be published in 2010.

The European guideline positions itself at the other extreme from JNC 7 in suggesting that five major classes of BP-lowering drugs (ACE inhibitors, ARBs, β -blockers, CCBs, and diuretics) are suitable as initial therapy. The choice in part reflects the physician's assessment of concomitant conditions and specific indications and contraindications for different drug classes in an individual patient.⁸

The British Hypertension Society and U.K. NICE guideline have adopted a different and perhaps more pragmatic approach. Their analysis of the data suggested that a CCB (C) or alternatively a thiazide-type diuretic (D) would most likely deliver the most effective initial BP lowering in older people (i.e., ≥ 55 years), whereas an ACE inhibitor or an ARB (A) would be the preferred initial therapy for younger patients (< 55 years), with the caveat that C or D would be the preferred therapy for people of black African origin at any age (Fig. 35.12).¹⁰ The rationale for this recommendation was founded on the observation that plasma renin levels fall as people age and are lower in blacks at any age. Therefore, drugs that target the renin system are more likely to be more effective initial therapy in the younger patients with higher renin activity, whereas the converse is true with aging.

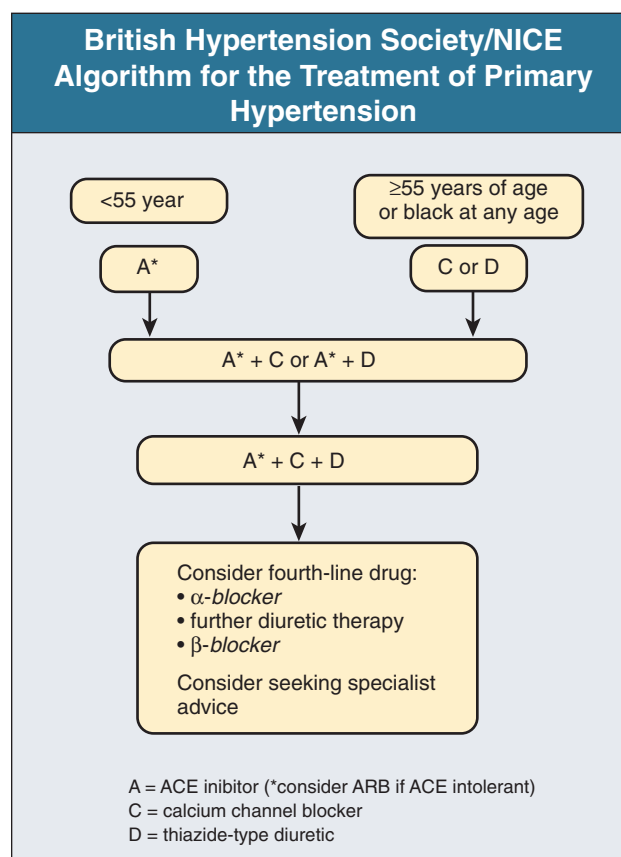

Figure 35.12 British Hypertension Society/NICE algorithm for the treatment of primary hypertension. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker. (Modified from the NICE hypertension guideline, reference 10.)

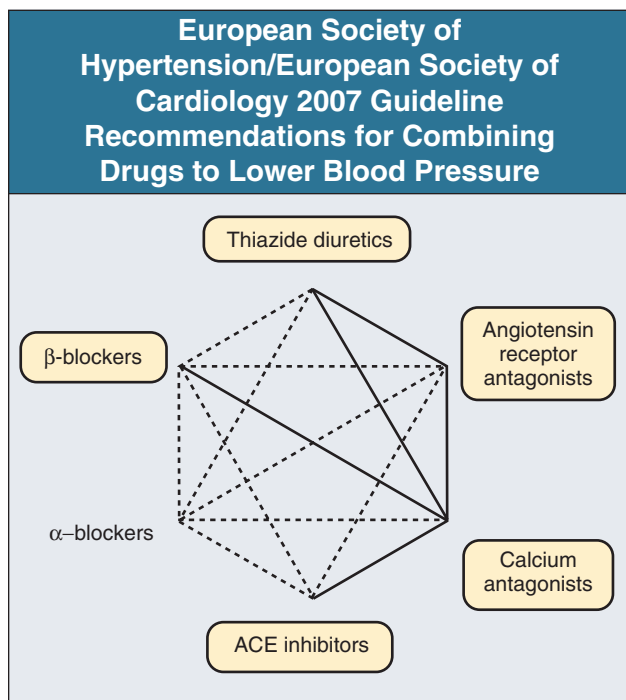

Figure 35.13 European Society of Hypertension/European Society of Cardiology 2007 guideline recommendations for combining drugs to lower blood pressure. The preferred combinations in the general hypertensive population are represented as thick lines. Classes of agents proven to be beneficial in controlled intervention trials are enclosed in boxes. ACE, angiotensin-converting enzyme. (From reference 8.)

These guidelines also recommended against the use of β -blockers as a preferred initial therapy (especially for older patients), unless there are compelling indications, because (1) they appeared less effective at reducing the risk of stroke than the alternatives, (2) they were associated with an increased risk for development of diabetes, and (3) they were the least cost-effective treatment option for primary hypertension.^{10,25}

Combination Therapy for Controlling Blood Pressure

All guidelines recognize that combinations of BP-lowering drugs are often required to achieve recommended BP goals, especially for those with high CVD risk or comorbidities who are targeted to lower goals. The European guidelines provide a diagram to illustrate suitable combinations of treatment but do not specify which combination might be preferred (Fig. 35.13). The U.S. JNC 7 guideline recommended that whatever combination is used, it should usually include a diuretic, consistent with the fact that they had also recommended initial therapy usually with a diuretic (Fig. 35.14). The British guideline provides explicit guidance on preferred combinations of treatment at step 2 (i.e., A + C or A + D) and step 3 (i.e., A + C + D) (see Fig. 35.12).

Recently, the ACCOMPLISH trial specifically evaluated whether the type of combination therapy is important in influencing clinical outcomes by comparing two different single-pill combinations, an ACE inhibitor plus a thiazide diuretic versus the same ACE inhibitor combined with a CCB, in a high-risk group of patients.³¹ There was a significant (~20%) reduction in the primary endpoint in favor of the ACE-CCB treatment group, and all components showed this trend. This difference does not appear to be due to differences in BP control between groups.

Whatever the explanation for the difference in primary outcomes between treatment groups, the ACCOMPLISH study has established that combining a CCB with ACE inhibitor or presumably other forms of RAAS blockade is an effective treatment option for high-risk patients with hypertension. This result should not lead to a downgrading of diuretic therapy as a preferred component of two-drug combinations. Physicians still need choices—not every patient will tolerate a CCB or a diuretic. Most physicians would choose some form of RAAS blockade (ACE inhibitor, ARB, or DRI) as part of the preferred treatment strategy for hypertension. The data from ACCOMPLISH, alongside a wealth of data with diuretics, provide two excellent evidence-based options to combine with RAAS blockade, a diuretic or a CCB, and perhaps both in those with more resistant hypertension.

Initial Therapy with a Two-Drug Combination “Low-dose” two-drug combination therapy has been recommended in the European and American hypertension guidelines for the treatment of patients whose BP is more than 20/10 mm Hg above their goal BP and therefore unlikely to be controlled with monotherapy (see Fig. 35.12). The concept of initial therapy with a two-drug combination has in part been driven by concern that the upward titration of treatment in people at high risk may be too slow and leave them at risk for too long. A two-drug combination is also logical because the response to a single drug is often limited by counteractivation of pressor systems that limit the effectiveness of monotherapy. This also explains why many BP-lowering drugs in monotherapy have a relatively flat dose-response. For example, sodium and water loss due to diuretics or vasodilation with CCBs will activate RAAS, which limits the BP lowering. Thus, low-dose two-drug combination therapy is likely (1) to produce much greater BP lowering, (2) to reduce heterogeneity in the BP-lowering response, and (3) to have a more effective dose-response to upward titration of either component. The main concern has been safety and tolerability with regard to potentially large initial BP falls in treatment-naïve patients. It seems inevitable that low-dose combinations will become more popular as an initial therapy option for a greater proportion of patients, with the preferred combinations likely to be RAAS blockade plus diuretic and RAAS blockade plus CCB.

Combining RAS Blockade?

The popular view that RAAS blockade is an important way of preventing or regressing hypertension-mediated structural and functional damage led to suggestions that different strategies to block RAAS should be combined to deliver more effective RAAS blockade. The recent ONTARGET trial demonstrated that an ACE inhibitor plus ARB combination was no more effective than ACE inhibitor alone at preventing major CV events in a high-risk population of patients.²⁸ This suggests that this combination of ACE inhibitor plus ARB should not be routinely used for the management of patients with primary hypertension or patients at high CV risk in general. Further studies are required to better define the place for alternative options for dual RAS blockade (e.g., ACE inhibitor or ARB plus direct renin inhibition). Such studies are ongoing.

Resistant Hypertension

Resistant hypertension has been defined as BP that remains above goal in spite of the concurrent use of three antihypertensive agents of different classes. The U.S. guidance suggests that one of the three agents should be a diuretic and all agents should be prescribed at optimal doses.¹⁹ The definition could have been

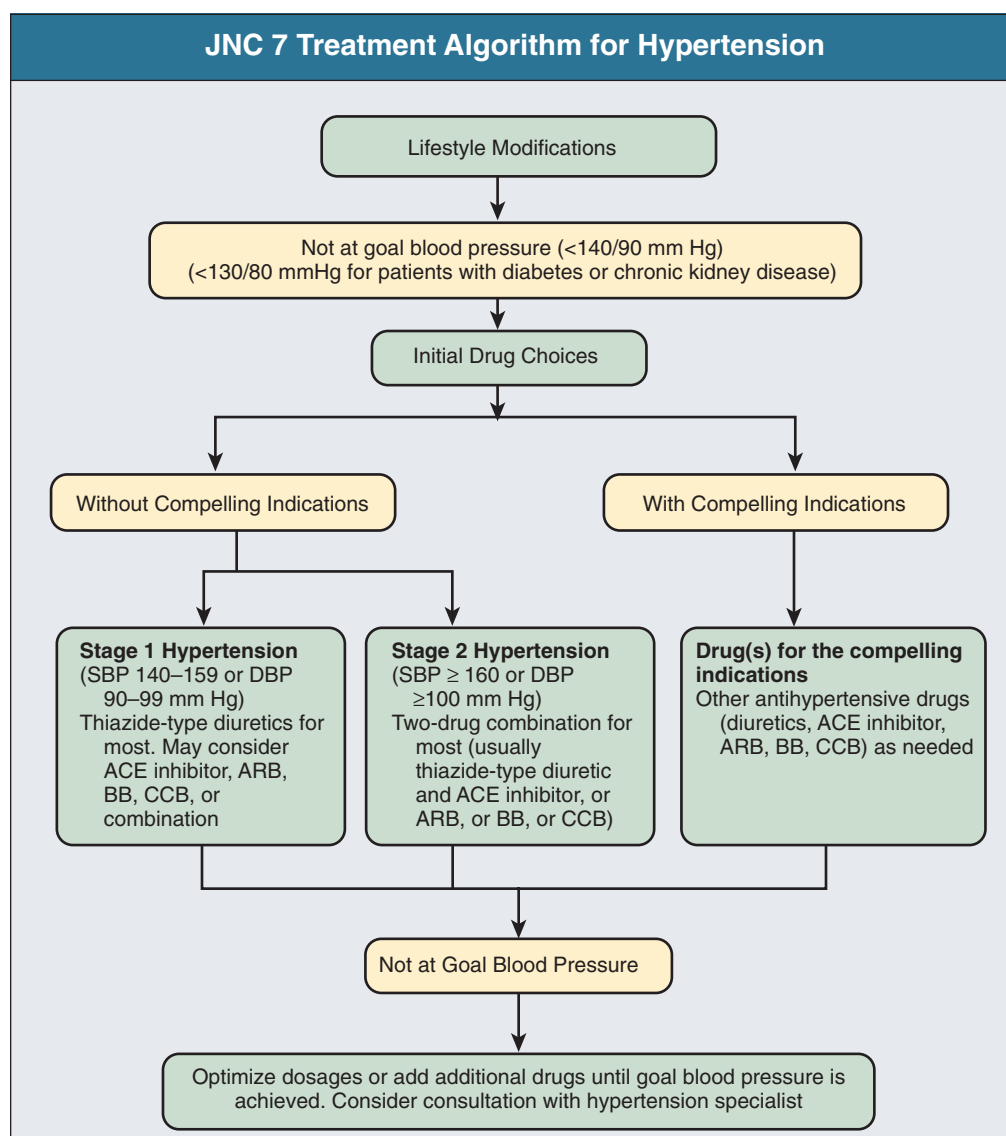

Figure 35.14 JNC 7 treatment algorithm for hypertension. DBP, diastolic blood pressure; SBP, systolic blood pressure. Drug abbreviations: ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BB, β -blocker; CCB, calcium channel blocker. (From reference 7.)

even more prescriptive by suggesting that the three drugs would usually comprise A + C + D in best tolerated doses. Most of these people will be older, often obese, and invariably with evidence of target organ damage. In the absence of evidence of target organ damage, white coat hypertension should be excluded by 24-hour ambulatory monitoring. Other causes of resistant hypertension should also be considered (Fig. 35.15).¹⁶

The evidence base from which to define the optimal treatment of resistant hypertension is limited. Most patients with drug-resistant hypertension are likely to be retaining sodium and will respond to further diuretic therapy. This can be achieved by further increasing the dose of the thiazide diuretic or using low-dose spironolactone (e.g., 25 mg/day) or amiloride (10 to 20 mg/day), with careful monitoring of electrolytes. Recent data suggest that a selective endothelin type A receptor antagonist (darusentan) is effective at reducing BP in people with resistant hypertension but should be avoided in people with a prior history of heart failure or left ventricular dysfunction.³² For some patients with severe drug-resistant hypertension, it may be necessary to use a combination of minoxidil, loop diuretic, and β -blocker to improve BP control. Beyond drug therapy, a novel approach

to treatment of patients with resistant hypertension by use of radiofrequency ablation of renal sympathetic nerves was recently reported and requires further evaluation.³³

Medication to Reduce Cardiovascular Risk

BP should not be treated in isolation, and treatment should be considered part of a more comprehensive strategy to reduce CVD risk. Patients at high risk, that is, those with established CVD, target organ damage, or diabetes, and those with a calculated CVD risk that is elevated (e.g., $\geq 20\%$ during 10 years) should be considered for additional interventions to reduce risk.³⁴ These include reinforcement of lifestyle advice, especially smoking cessation, and treatment with statin therapy to further reduce the risk of stroke and coronary disease. In recent studies, routine use of statins to reduce total cholesterol values by 40 mg/dl (~ 1 mmol/l) has been associated with a reduction in the risk of ischemic heart disease events by about one third and of stroke by about one fifth, over and above the benefit already accrued from BP lowering.^{34,35} Moreover, the relative risk reduction associated with statin therapy in higher risk hypertensive patients was not dependent on a high baseline cholesterol value. Higher risk

Considerations in the Patient with Resistant Hypertension			
Considerations in the Patient with Resistant Hypertension	Secondary Causes of Resistant Hypertension	Concomitant Drugs that May Raise BP and Counter Antihypertensive Agent Effects	Causes of “Pseudoresistant Hypertension”
Demographics Older age; especially >75 yrs Obesity Women > men More common in blacks Excess dietary sodium High baseline BP and chronicity of uncontrolled hypertension Concomitant disease Target organ damage: LVH or CKD Diabetes Atherosclerotic vascular disease Aortic stiffening	Common causes Primary hyperaldosteronism Atherosclerotic renovascular disease Sleep apnea Chronic kidney disease Uncommon causes: Pheochromocytoma Aortic coarctation Cushing's disease Hyperparathyroidism	Prescribed medicines Oral contraceptives Nonsteroidal anti-inflammatory drugs Sympathomimetic agents (e.g., decongestants in proprietary cold remedies) Cyclosporine Erythropoietin Corticosteroids (e.g., prednisone, hydrocortisone) Nonprescription: Drug abuse (e.g., cocaine, amphetamines) Excess licorice ingestion Herbal remedies (e.g., ephedra, also known as mahuang)	Errors in BP measurement (i.e., too small BP cuff for arm circumference) White coat hypertension Check BP with ABPM or home BP measurements Poor patient adherence to medications Check BP response to directly observed medication

Figure 35.15 Considerations in the Patient with Resistant Hypertension. BP, blood pressure; ABPM, ambulatory blood pressure monitoring; CKD, chronic kidney disease; LVH, left ventricular hypertrophy. (Modified from reference 18.)

hypertensive patients should also be considered for treatment with antiplatelet drugs once BP has been controlled.

Follow-up

In the early stages of treatment, the frequency of monitoring will be determined by the response to therapy, the comorbidities, and the complexity of the treatment regimen required to control the BP. Once BP is controlled, patients should be re-evaluated at least annually for a formal review, and most will be re-evaluated every 6 months. Patients are increasingly monitoring their own BP in the intervening periods, and this trend is likely to increase.

Withdrawal of Therapy

Most patients with hypertension require lifelong therapy. Some with grade 1 hypertension who make major adjustments to their lifestyle may obtain sufficient fall in their BP to warrant safe withdrawal of monotherapy. However, patients with target organ damage or those at high CVD risk should not usually have their therapy withdrawn unless there is a compelling clinical reason to do so.⁹ In patients with previously severe hypertension that has subsequently been well controlled, treatment withdrawal may not always result in an immediate increase in BP. After treatment withdrawal, BP can sometimes take many months to progressively rise back to dangerously high pretreatment values. Any patient who discontinues therapy must remain under review with regular monitoring of BP. All but a very few will require treatment again.

Indications for Specialist Referral

Referral to a specialist center is sometimes indicated for the management of hypertension. Indications include uncertainty about the decision to treat, investigations to exclude secondary

hypertension, severe and complicated hypertension, and resistant hypertension (Fig. 35.16).

Hypertension in Specific Groups of Patients

Hypertension in People of Black African Origin Hypertension is more prevalent in blacks, is associated with more target organ damage, and consequently carries a worse prognosis, with a particularly high risk of stroke.³⁷ Black patients as a group tend to respond better to diuretics, CCBs, and dietary salt restriction than caucasian patients do. ACE inhibitors, ARBs, and β -blockers are generally less effective as initial therapy but become more effective in combination with diuretics or CCBs.

Hypertension in Older People If a BP of 140/90 mm Hg or higher is used to define hypertension, then more than 70% of people older than 60 years will be hypertensive, the majority of these patients having isolated systolic hypertension.³⁸ Surveys suggest that physicians consistently underestimate the risks and undertreat hypertension in older people. There are, however, some important considerations in treating older people.

1. The arterial wall stiffening that gives rise to systolic hypertension and increased pulse pressure (isolated systolic hypertension) is also associated with impaired baroreflex sensitivity with increased risk of orthostatic hypotension. Thus, it is important to record lying and standing BP in the elderly.
2. Estimated GFR declines with age, and renal conservation of sodium and fluid in the face of depletion is impaired. Elderly patients are therefore more subject to volume depletion as a result of diuretic therapy.
3. Clearance of drugs and their active metabolites is decreased as a result of declining hepatic and renal function.
4. Cardiac function and reserve are often reduced, and patients are therefore much more likely to develop cardiac failure. This explains why endpoint trials of hypertension

Indications for Specialist Referral for Patients with Hypertension

Urgent treatment needed

Accelerated hypertension (severe hypertension with grade III–IV retinopathy)
Particularly severe hypertension (>220/120 mm Hg)
Impending complications (e.g., transient ischemic attack, left ventricular failure)

Possible underlying cause

Any clue in history or examination of a secondary cause (e.g., hypokalemia with increased or high-normal plasma sodium)
Elevated serum creatinine
Proteinuria or hematuria
Sudden onset or worsening of hypertension
Resistance to multidrug regimen (i.e., ≥ 3 drugs)
Young age (any hypertension <20 years; needing treatment <30 years)

Therapeutic problems

Multiple drug intolerance
Multiple drug contraindications
Persistent nonadherence or noncompliance

Special situations

Unusual blood pressure variability
Possible white coat hypertension
Hypertension in pregnancy

Figure 35.16 Indications for specialist referral for patients with hypertension.

treatment have consistently shown reductions in morbidity and mortality from cardiac failure.

5. Comorbidity is much more common.
6. Communication and adherence with therapy may be more difficult with decline in cognitive function. Some evidence from clinical trials suggests that this decline may be retarded by antihypertensive treatment.

Despite these considerations, the elderly tolerate BP-lowering medications well, and the benefits of BP reduction are impressive with regard to reductions in morbidity and mortality due to stroke, ischemic heart disease, and heart failure. As a general rule, drug regimens should be as simple as possible and dosages increased more gradually. The greatest danger results from lowering of pressure too rapidly. Until recently, there was uncertainty about the risks and benefits of treating hypertension in the very elderly, that is, those older than 80 years. The HYVET study¹⁷ in this age group confirmed that treatment is well tolerated and associated with impressive reductions in the risk of stroke, heart failure, and mortality. Thus, there is no reason to manage very elderly patients any differently from those who are not as old. Biologic rather than chronologic age should be the deciding factor in initiating antihypertensive treatment.

Evaluation and Treatment of Hypertensive Urgencies and Emergencies

Pantelis A. Sarafidis, George L. Bakris

The term *malignant hypertension* first appeared in 1928¹ to describe patients with very high blood pressure (BP) values. “Malignant” was used to compare the prognosis of these patients with that of most cancers because they had such rapid target organ deterioration, such as retinal hemorrhages or exudates and papilledema, usually associated with encephalopathy, acute renal failure, and microangiopathic hemolytic anemia.^{2,3} Dramatic advancements of both in-hospital and outpatient treatment of hypertensive emergencies, however, have led to an improved prognosis, that is, decrease in 1-year mortality from 80% in 1928 to 50% in 1955 and 10% in 1989.⁴ Thus, terms such as *malignant* and *accelerated* hypertension have been replaced by the terms *hypertensive emergency* and *hypertensive urgency*.

Marked elevations in systolic and diastolic BP, usually above 180/120 mm Hg, can be classified as either emergencies or urgencies. A hypertensive emergency is defined as marked elevation in BP complicated by evidence of acute life-threatening target organ damage, such as coronary ischemia, dissecting aortic aneurysm, pulmonary edema, hypertensive encephalopathy, cerebral hemorrhage, and eclampsia. In this clinical condition, BP should be reduced by at least 20 to 40 mm Hg within 10 to 30 minutes with parenteral drug therapy in an intensive care unit. Hypertensive urgency is a clinical setting of significant BP elevation, generally above 180/110 mm Hg, *without* life-threatening target organ dysfunction (i.e., papilledema, evidence of early heart failure, acute renal failure), although some evidence of target organ damage is usually present (hemorrhages and exudates in fundi, headaches). The approach to hypertensive urgency is a gradual BP reduction within hours, usually with oral medications.⁴⁻⁶

ETIOLOGY AND PATHOGENESIS

Both hypertensive emergencies and urgencies can develop *de novo* in normotensive individuals or complicate patients with underlying primary or secondary hypertension.^{3,4} Some hypertensive emergencies have acute BP elevations through increased activity of the renin-angiotensin system (RAS), for example, acute glomerulonephritis, renal crisis in patients with systemic sclerosis, or renal artery stenosis. In others, acutely elevated BP is the result of excess catecholamine release, such as from pheochromocytoma, monoamine oxidase inhibitor crisis, cocaine intoxication, or spinal cord injury. Occult renal artery stenosis is a frequent cause of elevated BP resulting in acute left ventricular failure or pulmonary edema. It may be difficult to differentiate whether BP elevation is the cause or the result of a hypertensive emergency. Thus, a careful diagnostic evaluation

of hypertensive emergencies and urgencies is essential to guide proper treatment.

The most common clinical setting for a hypertensive urgency is the chronic, often untreated or poorly controlled hypertensive patient whose usual BP is above 180/110 mm Hg. In many of these patients, chronically elevated BP does not affect target organ perfusion because of autoregulation. Autoregulation is the ability of blood vessels to dilate or to constrict in response to changes in perfusion pressure and thereby to maintain normal organ perfusion.⁷ This mechanism is present in the brain and kidneys and involves L-type calcium channels.⁷ Arteries from normotensive individuals can maintain flow over a wide range (80 to 150 mm Hg) of mean arterial pressures. Chronic elevations in BP cause compensatory functional and structural changes in the arteriolar circulation and shift the autoregulatory curve to the right, which allows hypertensive patients to maintain normal perfusion and to avoid excessive blood flow at higher BP levels.^{3,8} These features are established for the cerebral and renal circulation (Fig. 36.1).^{7,9}

Target organ damage associated with hypertensive emergency results from the inability of autoregulatory mechanisms to maintain normal perfusion pressures in vascular beds of the brain and kidney when BP rises to values above the autoregulatory range.⁸ This causes endothelial injury that results in increased vascular wall permeability, cell proliferation, and activation of platelets and the coagulation cascade, leading to further vascular damage and tissue ischemia. This is coupled with activation of hormonal systems and release of vasoactive substances (RAS, catecholamines, endothelin, vasopressin) that maintain a vicious circle between elevated BP and vascular injury.¹⁰ Other mechanisms that contribute to impaired autoregulation include progressive disease of arterioles, observed in both cerebral and renal circulations as well as when autoregulation is pharmacologically inhibited (such as with dihydropyridines or furosemide). In most cases, the development of a hypertensive emergency occurs in the presence of chronic hypertension and relates to the disease status of the arterioles that already have some impaired autoregulation.

The structural changes associated with hypertensive emergencies are fibrinoid necrosis of small arteries and arterioles in the brain and kidney (Fig. 36.2), coupled with findings of injury of the afflicted organs (e.g., cerebral edema).^{8,11}

EPIDEMIOLOGY

The exact incidence of hypertensive emergencies and urgencies as well as their demographic distribution is not known. One

Figure 36.1 Renal autoregulation. Relationship of systemic to glomerular pressure in the setting of normal or abnormal renal autoregulation.

Figure 36.2 Fibrinoid necrosis, noted as a pink homogeneous material, in the renal interlobar artery of a patient with severe hypertensive emergency.

study with more than 14,000 emergency department visits during 12 months showed that hypertensive urgencies accounted for 76% and emergencies for 24% of hypertension-related visits.¹² In this study, the most common presentations of hypertensive emergencies were associated with cerebral infarction (24.5%), acute pulmonary edema (22%), hypertensive encephalopathy (16%), and acute heart failure (14%), followed by myocardial infarction (12%), cerebral hemorrhage (5%), eclampsia (5%), and aortic dissection (2%). Note that scleroderma can also present as a hypertensive emergency but is rare. In a different series of 435 hypertensive emergency department visits, 40% were hypertensive urgencies, almost all with some degree of preexisting kidney disease, and 60% were emergencies.¹³ Hospitalization for hypertensive emergency occurs at a rate of 1 to 2 cases per million per year in the United States.⁸

In developed countries, widespread use of antihypertensive agents has reduced the incidence of hypertensive emergencies. This hypothesis is supported from several indirect observations.^{8,10} Use of any antihypertensive drug reduces the risk of hypertensive emergencies because poor treatment compliance and outpatient BP control are predictors of subsequent hypertensive crises. In a series of 100 patients hospitalized for severe hypertension, 93% had previously stopped prescribed antihypertensive drugs or were unable to access health care resources. Further, hospitalization for hypertensive emergency is more

Diagnostic Evaluation for Hypertensive Emergencies and Urgencies	
History	Previous diagnosis and treatment of hypertension Symptoms, previous diagnoses and treatment of cardiac, cerebral, and visual damage Intake of pressor agents: sympathomimetics, illicit substances
Repeated blood pressure measurements (first measurement in both arms)	
Physical examination	Cardiac Vascular Pulmonary Neurologic Optic fundi
Laboratory studies	Full blood count, urinalysis, creatinine, urea, electrolytes Plasma renin activity, aldosterone, and catecholamines if secondary hypertension is suspected
Electrocardiography	
Chest radiograph	
Further investigations (according to the clinical presentation)	Brain CT scan or MRI Echocardiography (transthoracic, transesophageal) Thoracoabdominal CT scan or MRI Abdominal ultrasonography

Figure 36.3 Diagnostic evaluation for hypertensive emergencies and urgencies. CT, computed tomography; MRI, magnetic resonance imaging.

common in developing countries, ethnic minorities (African Americans and Hispanics in the United States), and individuals with low socioeconomic status.¹⁴

DIAGNOSIS

The primary goal of the diagnostic process is differentiation of a true hypertensive emergency from urgency, as the respective therapeutic approaches are different. The second goal is quick assessment of the type and the severity of ongoing target organ damage. In some hypertensive emergencies, information from history (acute head trauma, preeclampsia, scleroderma) or overt symptoms and signs (chest or back pain, dyspnea, throbbing abdominal mass) may guide the diagnosis; whereas in other cases (severe hypertension with altered mental status), the evaluation is more protracted.

The diagnostic approach begins with the patient's history, with attention to duration, severity, and treatment of preexisting hypertension and associated conditions (Fig. 36.3).^{6,10} BP measurements should be performed in both arms (if possible, in both sitting and standing positions) and a leg according to current guidelines (see Chapter 32).^{2,5} A careful cardiac, pulmonary, peripheral vessel, and neurologic examination with assessment of mental status should follow, coupled with a thorough fundoscopic examination for hemorrhages, exudates, and papilledema. Secondary hypertension should not be missed in this initial examination. For example, an abdominal bruit suggests renovascular hypertension, a palpable abdominal mass suggests abdominal aneurysm or polycystic kidneys, a radial-femoral pulse delay suggests aortic coarctation, abdominal striae are observed with central obesity and Cushing's syndrome, and exophthalmos suggests hyperthyroidism.

The basic laboratory studies in a hypertensive emergency include a complete blood count with peripheral smear, urinalysis, creatinine concentration, urea concentration, and electrolyte values.^{6,10} Assessment of kidney function and, if possible, comparison with a patient's recent measurement is very important. Severe hypertension accompanied by acute deterioration in kidney function, microscopic hematuria, or nephritic urine sediment suggests acute glomerulonephritis. If a secondary form of hypertension is suspected, samples for plasma renin activity, aldosterone concentration, and 24-hour urine metanephrine values should also be drawn *before* initiation of treatment. Testing should be performed with the patient supine, and ideally the patient should not be receiving β -blockers, especially labetalol, as they will give false-positive readings of metanephrine values. Electrocardiography to rule out myocardial ischemia and left ventricular strain or hypertrophy as well as chest radiography should be performed in every patient.⁶

Neurologic syndromes associated with hypertension (subarachnoid hemorrhage, intracerebral hemorrhage, thrombotic stroke, and hypertensive encephalopathy) are difficult to distinguish from one another. Computed tomography (CT) or magnetic resonance imaging (MRI) provides a definite diagnosis of a hemorrhagic or thrombotic stroke. Echocardiography, thoracoabdominal CT or MRI, or abdominal ultrasound may be needed in suspected aortic dissection or pheochromocytoma.⁶

TREATMENT

General Principles for Management of Hypertensive Emergencies

Although therapy with parenteral antihypertensive agents may be initiated in the emergency department, patients with a hypertensive emergency should be admitted to an intensive care unit for continuous BP monitoring, clinical surveillance, and continued parenteral administration of an appropriate agent (Figs. 36.4 and 36.5). Specific BP levels do not determine the severity and the emergency of the situation because the autoregulatory structural and functional changes may vary between individuals, such that some individuals may develop target organ damage at lower BP. Understanding of autoregulation is crucial for therapeutic decisions; sudden lowering of BP into a "normal" range could lead to inadequate tissue perfusion.⁸ There is evidence that abrupt lowering of BP is harmful. For example, the use of sublingual nifedipine may precipitate stroke or shunt blood away from the penumbra of the brain, resulting in cognitive dysfunction.¹⁵ Thus, the goal of antihypertensive therapy is not to rapidly normalize BP but to prevent target organ damage by gradually reducing BP while minimizing the risk of hypoperfusion.

For most hypertensive emergencies, the mean BP should be reduced by no more than 20% to 25% within the first few minutes to an hour.^{5,6} A diastolic BP target between 100 and 110 mm Hg or a reduction of 25% compared with the initial baseline, whichever is higher, is appropriate to be achieved within the next 2 to 6 hours. Reduction of BP diastolic pressure to less than 90 mm Hg or by 35% or more of the initial mean BP has been associated with major organ dysfunction, coma, and death.

If the level of BP reduction is well tolerated and the patient clinically stable, further gradual reductions toward levels below 140/90 mm Hg should be implemented within the next 24 to 48 hours. Typically, a long-acting oral calcium channel blocker (CCB) is given along with either an α - and β -blocker like carvedi-

dilol or nebivolol or RAS blocker, and the intravenous medication is gradually reduced during 1 to 2 hours.⁸

An important consideration before initiation of intravenous therapy is assessment of the patient's volume status. Because of pressure natriuresis, patients with hypertensive emergencies may be volume depleted, and restoration of intravascular volume may help restore organ perfusion and prevent a precipitous fall in BP.¹⁶

Major exceptions to these treatment recommendations include (1) patients with acute stroke, in whom there is no clear evidence to support immediate BP lowering and a more cautious approach is needed (see Chapter 40); (2) patients with aortic dissection, who should have their systolic BP lowered to below 100 mm Hg if tolerated; and (3) patients in whom BP should be lowered to enable the use of thrombolytic agents.^{5,6,16}

A systematic review of four hypertensive emergency and 15 urgency studies suggested that several medications are effective for lowering BP in a hypertensive emergency (see Fig. 36.4). However, the authors concluded that because of the lack of large randomized controlled trials, questions including appropriate duration of follow-up and whether any of the agents provide mortality or morbidity benefits remain unanswered.¹⁷ A recent meta-analysis of 15 trials¹⁸ showed some minor differences in the degree of BP lowering when one class of antihypertensive drug was compared with another, but the clinical significance is unknown.

Specific Aspects of Antihypertensive Drug Use for Hypertensive Emergencies (see Fig. 36.5)

For several years, sodium nitroprusside was considered the first-choice drug for all hypertensive emergencies. It is easily titrated, is inexpensive, and has a long record of effectiveness in treating hypertensive emergencies of nearly all types.^{6,8,10,19} Limitations of nitroprusside use include the need for invasive BP monitoring and its metabolic products (thiocyanate and cyanide), which contraindicate its use in pregnancy and limit the time used (48 hours) in patients with renal or hepatic dysfunction. Nitroprusside is reported to increase intracranial pressure in high doses, to obliterate cerebral autoregulation, and to reduce regional coronary blood flow, which could limit its usefulness in patients with neurologic complications or acute coronary syndromes. Nitroprusside infusion typically begins at 0.3 $\mu\text{g}/\text{kg}/\text{min}$ and increases by 0.2 to 1.0 $\mu\text{g}/\text{kg}/\text{min}$ every 3 to 5 minutes until BP reaches the target range. Because of the toxicity issues, some authors suggest that nitroprusside be used only when alternative drug choices are not available and not exceed a dose of 2 $\mu\text{g}/\text{kg}/\text{min}$.¹⁶

Two other drugs approved in the United States for hypertensive emergencies are increasingly used. Nicardipine is a dihydropyridine CCB with intermediate onset and duration of effect, prolonged half-life, and strong cerebral and coronary vasodilatory activity. It is useful for most hypertensive emergencies, especially in patients with coronary artery disease. Nicardipine interacts with inhalant anesthetics.^{8,16,19} Fenoldopam mesylate is a selective agonist of dopaminergic 1 receptors located mainly in the renal and splanchnic arteries with lesser density in the coronary and cerebral arteries.^{8,10,19} Intravenous fenoldopam does not cross the blood-brain barrier and has no central nervous system activity because it is a poorly lipid soluble molecule. In clinical trials compared with sodium nitroprusside, fenoldopam demonstrated similar BP-lowering efficacy and beneficial renal effects (increased diuresis, natriuresis, and creatinine clearance, and it has a very short half-life).²⁰ Thus, fenoldopam is mostly useful for BP

Treatment of Hypertensive Emergencies						
Drug	Mechanism of Action	Dose	Onset of Action	Duration of Action	Adverse Effects*	Special Indications
Vasodilators						
Sodium nitroprusside	↑ Cyclic GMP, blocks intracellular Ca^{2+} increase	0.25–10 $\mu\text{g/kg/min}$ IV infusion†	Immediate	1–2 min	Nausea, vomiting, muscle twitching, sweating, thiocyanate and cyanide intoxication	Most hypertensive emergencies; caution with high intracranial pressure, hepatic or renal failure
Nicardipine hydrochloride	Calcium channel blocker	5–15 mg IV every hour	5–10 min	15–30 min, may exceed 4 h	Tachycardia, headache, flushing, nausea, vomiting, local phlebitis	Most hypertensive emergencies except acute heart failure; caution with coronary ischemia
Fenoldopam mesylate	Dopamine 1 receptor agonist	0.1–0.3 $\mu\text{g/kg/min}$ IV infusion	>5 min	30 min	Tachycardia, headache, nausea, flushing	Most hypertensive emergencies; caution with glaucoma
Nitroglycerin	↑ Nitrate receptors	5–100 $\mu\text{g/min}$ IV infusion	2–5 min	5–10 min	Headache, vomiting, methemoglobinemia, tachyphylaxis, tolerance with prolonged use	Coronary ischemia, pulmonary edema
Hydralazine hydrochloride	Opens K^{+} channels	10 IV	10–20 min	1–4 h	Tachycardia, flushing, headache, vomiting, aggravation of angina	Eclampsia
Enalaprilat	ACE inhibitor	1.25–5 mg every 6 h IV	15–30 min	6–12 h	Precipitous fall in BP in high-renin states, variable response, acute renal failure	Acute left ventricular failure; avoid in acute myocardial infarction
Diazoxide	Direct-acting vasodilator	50–150 mg every 5 min IV or 15–30 mg/min IV infusion	1–5 min	4–12 h	Nausea, flushing, reflex sympathetic stimulation, aggravation of angina, sodium retention, hyperglycemia	Avoid in angina, acute myocardial infarction, aortic dissection
Clevidipine butyrate	CCB	1–2 mg/h IV infusion Increase every 5–10 min up to 16 mg/h	2–4 min	5–15 min	Tachycardia, headache, flushing, heart failure deterioration	Most hypertensive emergencies except acute heart failure; caution with severe aortic stenosis
Adrenergic inhibitors						
Labetalol hydrochloride	α_1 , β -Blocker	20–80 mg IV bolus every 10 min or 0.5–2 mg/min IV infusion	5–10 min	3–6 h	Nausea, vomiting, scalp tingling, bronchoconstriction, dizziness, heart block, congestive heart failure	Most hypertensive emergencies except acute heart failure
Esmolol hydrochloride	β_1 -Blocker	0.5–2.0 mg/min IV infusion or 250–500 $\mu\text{g/kg/min}$ IV bolus, then 50–100 $\mu\text{g/kg/min}$ by infusion May repeat bolus after 5 min or increase infusion to 300 $\mu\text{g/min}$	1–2 min	10–30 min	Nausea, asthma, first-degree heart block, heart failure, thrombophlebitis	Aortic dissection, perioperative
Urapidil	α_1 -Blocker	12.5–25 mg IV bolus followed by 5–40 mg/h IV infusion	3–5 min	4–6 h	Headache, dizziness	Perioperative
Phentolamine	α -Blocker	5–15 mg IV bolus	1–2 min	10–30 min	Tachycardia, flushing, headache	Catecholamine excess
Treatment of Hypertensive Urgencies						
Captopril	ACE inhibitor	12.5–25 mg per os every 1–2 h	15–30 min	4–6 h	Angioedema, cough, acute renal failure	
Clonidine	Central α_2 -agonist	0.1–0.2 mg per os every 1–2 h	30–60 min	6–8 h	Sedation, dry mouth, bradycardia, rebound hypertension after withdrawal	
Labetalol	α_1 , β -Blocker	200–400 mg per os every 2–3 h	30–120 min	6–8 h	Bronchoconstriction, heart block, congestive heart failure	
Furosemide	Loop diuretic	20–40 mg per os every 2–3 h	30–60 min	8–12 h	Volume depletion, hyponatremia, hypokalemia	
Isradipine	CCB	5–10 mg per os every 4–6 h	30–90 min	8–16 h	Headache, tachycardia, flushing, peripheral edema	

*Hypotension may occur with all agents

†Requires light-resistant delivery system

Figure 36.4 Pharmacologic agents for treatment of hypertensive emergencies and urgencies. *Hypotension may occur with all agents. †Requires light-resistant delivery system. ACE, angiotensin-converting enzyme; BP, blood pressure; CCB, calcium channel blocker; GMP, guanosine monophosphate.

Management of Specific Types of Hypertensive Emergencies				
Type of Emergency	First Choice of Drug(s)	Second Choice/Additional Drug(s)	Drugs to Be Avoided	Aim of BP Reduction
Neurological				
Hypertensive encephalopathy	Nicardipine, fenoldopam, labetalol	Esmolol, urapidil, nitroprusside*		20–25% reduction in mean BP over 1–2 hours
Ischemic stroke	Nicardipine, labetalol, nitroprusside*	Esmolol, urapidil		Reduction of BP if above 220/120 mmHg (mean BP >130 mmHg) by no more than 10%–15% within the first 24 hours to avoid impairing cerebral blood flow in the penumbra.
Intracerebral hemorrhage	Nicardipine, labetalol, nitroprusside*	Esmolol, urapidil, nimodipine for subarachnoid haemorrhage		Decrease in BP below 185/110 mmHg to prevent further bleeding and hypoperfusion. For subarachnoid haemorrhage in normotensive patients reduction to systolic BP 130–160 mmHg.
Cardiac				
Coronary ischemia/infarction	Nitroglycerin or nitroprusside*	Nicardipine; labetalol, esmolol if heart failure absent	Diazoxide, hydralazine	Improvement in cardiac perfusion
Heart failure/pulmonary edema	Nitroglycerin or nitroprusside* or fenoldopam	Enalaprilat; diuretics	Diazoxide, hydralazine; β -blockers	Decrease in afterload
Aortic dissection	Labetalol or combination of esmolol with fenoldopam or nicardipine	Nitroprusside*	Diazoxide, hydralazine	Decrease of aortic wall stress with systolic BP reduction <100–120 mmHg in 20 minutes (if possible)
Renal				
Acute glomerulonephritis, collagen-vascular renal disease, or renal artery stenosis	Fenoldopam	Nicardipine, labetalol; diuretics for volume overload	Sodium nitroprusside; RAS blockers (use initially for scleroderma but after renal function stabilizes for other conditions)	Reduction in vascular resistance and volume overload without compromise of renal blood flow or GFR
Catecholamine Excess States				
Pheochromocytoma	Phentolamine or labetalol	β -blocker in the presence of phentolamine	Diuretics	Control of BP paroxysms from sympathetic stimulation
Ingestion of cocaine or other sympathomimetic	Phentolamine or labetalol	β -blocker in the presence of phentolamine	Diuretics	Control of BP paroxysms from sympathetic stimulation
Perioperative/Postoperative Hypertension				
Coronary artery surgery	Nitroglycerin	Esmolol, labetalol, sodium nitroprusside*, fenoldopam, nicardipine, urapidil, clevidipine		Protection against target organ damage and surgical complications (keep BP <140/90 or mean BP 105 mmHg)
Non-cardiac surgery	Esmolol, labetalol, nitroprusside, fenoldopam, nicardipine, urapidil, nitroglycerin, clevidipine			Protection against target organ damage and surgical complications
Pregnancy-related				
Eclampsia	Hydralazine, labetalol, long-acting nifedipine	MgSO ₄ , methyldopa	Nitroprusside*, ACE inhibitors, ARBs	Control of BP (typically <90 mmHg diastolic but often lower) and protect placental blood flow

Figure 36.5 Management of specific types of hypertensive emergencies. *Nitroprusside obliterates cerebral autoregulation, fenoldopam does not and hence is preferred if cost not prohibitive. Nimodipine has also been shown to be effective in ischemic strokes. ACE, angiotensin-converting enzyme; ARBs, angiotensin receptor blockers; BP, blood pressure; RAS, renin-angiotensin system.

reduction in patients with renal impairment, those with heart failure, and those undergoing vascular surgery. Fenoldopam infusion typically begins at 0.1 µg/kg/min and is increased at 20-minute intervals by 0.1 to 0.2 µg/kg/min, with a maximum dose of 1.5 µg/kg/min. Fenoldopam must be administered with caution, if at all, to patients with glaucoma, as it increases intraocular pressures. In relation to nitroprusside, nicardipine and fenoldopam appear much safer, but they are both more expensive.

Labetalol is a nonselective α_1 - and β -blocker (in the ratio of 1:7, given intravenously) that can be used in many hypertensive emergencies as it has rapid onset of action, potent and sustained effect, and low toxicity. It reduces peripheral vascular resistance without a reflex increase in systolic volume. Its main indications are aortic dissection, acute coronary syndromes, hypertensive encephalopathy, and adrenergic crisis. It is contraindicated in patients with heart failure, heart block, and chronic obstructive pulmonary disease.^{6,10,16}

A newer agent that may provide a useful alternative for the treatment of hypertensive crises is clevidipine, a third-generation dihydropyridine CCB, developed for use in clinical settings in which tight BP control is crucial. Clevidipine is a short-acting selective arteriolar vasodilator that reduces peripheral resistance without affecting cardiac filling pressures. Its metabolism is not affected by renal or hepatic function.¹⁶ Recent trials demonstrate clevidipine to be effective and safe in the control of postoperative hypertension²¹ as well as in hypertensive emergencies.²² Clevidipine butyrate was approved in the United States at mid-2008 for BP reduction when oral therapy is not feasible or not desirable.

In hypertensive emergencies due to catecholamine excess states (pheochromocytoma, monoamine oxidase inhibitor crisis, cocaine intoxication), the use of diuretics should be avoided as these patients are usually volume depleted.

Treatment of Hypertensive Urgencies

There is no proven benefit from rapid BP reduction in asymptomatic patients without evidence of acute target organ damage; thus, all authorities agree that BP lowering should occur during a longer time than for a hypertensive emergency. BP reduction to levels within the range below 160/100 mm Hg may be accomplished within 2 to 4 hours in the emergency department with orally administered drugs.^{5,6} In short, the most important aspect of treatment of a hypertensive urgency is not achievement of BP goal but ensuring adequate follow-up, within a week, generally.^{5,8}

All agents that may be used to manage such conditions are listed in Figure 36.4. The choice of drugs for treatment of hypertensive urgency is much broader than for emergencies because almost all antihypertensive drugs lower BP effectively in a reasonable time. Captopril, clonidine, labetalol, and other short-acting antihypertensive drugs have been mostly used for this condition (see Fig. 36.4).^{5,6} Short-acting nifedipine, although once commonly used, is now contraindicated secondary to a higher incidence of stroke, myocardial infarctions, and deaths related to precipitous hypotensive episodes.²³

Oral clonidine (0.1 to 0.2 mg) is one of the most commonly used short-acting agents in this setting. However, patients should not be routinely discharged with clonidine if they have a history of nonadherence to drug regimens because of the risk of rebound hypertension if clonidine is abruptly stopped.

Furosemide can effectively lower BP if elevated pressure is related to volume, which is uncommon. A common physiologic

response of the kidney to elevated pressures is a natriuresis; hence, many such patients may be volume depleted. Longer acting CCBs, such as nifedipine XL, amlodipine, and sustained-release isradipine, also have a key role in longer term maintenance of this condition.⁶ Their disadvantage is that they inhibit renal autoregulation; thus, they should not be used as initial agents when BP is very high for routine management of hypertension. Because of their delayed onset of action, they also do not have a role in management of hypertensive emergencies.

Renovascular Hypertension and Ischemic Renal Disease

Stephen C. Textor, Barbara A. Greco

Renovascular disease with reduced perfusion of the kidney can produce several clinical syndromes, most commonly a rise in arterial pressure designated renovascular hypertension (RVH), with or without associated ischemic and hypertensive renal injury. RVH is usually caused by renal artery stenosis, and it is among the most common secondary forms of hypertension. Recognition that reduction of renal perfusion pressure activates a series of hormonal and neuronal responses that raise systemic arterial pressure remains one of the seminal observations in blood pressure (BP) regulation. Not surprisingly, high blood pressure in patients with renal artery stenosis frequently leads to the assumption that the stenosis is the cause of the hypertension. However, there are several clinical scenarios for patients with renal artery stenosis and hypertension: (1) true RVH, in which renal artery stenosis is the sole cause of the hypertension; (2) pure primary hypertension, in which renal artery stenosis is present but does not contribute to the hypertension at all; (3) primary hypertension with superimposed RVH due to renal artery stenosis; and (4) renal artery stenosis in concert with other causes of renal parenchymal damage in which the elevated arterial pressure may be driven by the pathophysiologic factors characteristic of renal injury. Final proof that a patient has RVH rests with the demonstration that the hypertension is improved or eliminated by removal of the stenosis by surgical or endovascular revascularization or by removal of the kidney distal to the stenosis.

The term *ischemic nephropathy* or ischemic renal disease (IRD) refers to the reduced glomerular filtration rate (GFR) associated with reduced renal blood flow beyond the level of renal autoregulatory compensation.¹ Over time, IRD can lead to renal atrophy and progressive renal impairment. As with RVH, establishment of the causal relationship between proximal renal artery stenosis and the development and progression of chronic kidney disease (CKD) is often difficult. Collateral renal blood supply can preserve renal viability in the face of proximal atherosclerotic renovascular occlusive disease, whereas small-vessel and parenchymal disease often coexist with main renovascular disease, particularly from atherosclerosis. Attempts to revascularize ischemic kidneys sometimes succeed in recovering renal function, but results are often disappointing. There are few predictors to guide therapeutic choices in these patients, who are often at high risk for complications of interventions.

Management of renovascular disease has been changing in recent years. New antihypertensive drug regimens are well tolerated and more effective. Endovascular procedures allowing percutaneous restoration of blood flow for atherosclerotic lesions are

also more widely available and safer than ever before.² Whereas a decade ago, most clinicians would have favored immediate revascularization for threatened kidneys, recent prospective trials have failed to demonstrate major advantages to revascularization compared with intensive medical therapy alone.³ As a result, there is justifiable uncertainty as to the optimal timing and intervention for many such patients. As with most vascular disease, the issue is most often one of timing, rather than simply deciding whether to rely on one therapy or another indefinitely.

DEFINITION, ETIOLOGY, AND EPIDEMIOLOGY

RVH is defined as a syndrome of elevated BP (systolic or diastolic) produced by a variety of conditions that interfere with arterial circulation to the kidneys. The majority of patients with RVH have significant main renal artery stenosis with concomitant reduced renal perfusion pressure. Most conditions arise with reduced perfusion to one kidney, while a second “contralateral” kidney is exposed to elevated systemic pressures, so-called two-kidney hypertension by analogy to experimental models of “two-kidney, one-clip hypertension” (see later discussion). [Figure 37.1](#) provides a list of conditions that can produce the syndrome of RVH by impairing renal blood supply. Many of these are rare, but all have in common a significant reduction in renal perfusion pressure. Other rarely encountered clinical conditions associated with the syndrome of RVH include unilateral renal trauma with associated intrarenal or perirenal hematoma (identified as a Page kidney), unilateral ureteral obstruction, atrophic pyelonephritis, and congenitally hypoplastic kidney. In some circumstances, both kidneys are affected (such as may happen with atheroembolic disease) or a solitary functioning kidney is affected, leading to a syndrome without a contralateral kidney, designated one-kidney RVH (see [Fig. 37.1](#)). Of the conditions that may produce the syndrome of RVH, main renal artery stenosis is by far the most common. The two major causes of main renal artery disease are fibromuscular dysplasia (FMD) and atherosclerotic renal vascular disease (ASRVD).

Fibromuscular Dysplasia

FMD produces aberrancies in luminal diameter of large and medium-sized renal arteries due to nonatherosclerotic arteriopathies. The lesions usually involve the mid to distal vessel beyond the first 2 cm from the aorta ([Fig. 37.2](#)). Clinical manifestations of renal artery FMD are summarized in [Figure 37.3A](#). The prevalence of clinically apparent renovascular FMD is estimated at

Renovascular Hypertension: Classification

“Two-Kidney Hypertension” (implies that a contralateral, nonaffected kidney is present)

- Unilateral fibromuscular dysplasia
- Unilateral atherosclerotic renovascular disease
- Renal artery aneurysm
- Renal artery embolism
- Traumatic arterial occlusion
- Arteriovenous fistula
- Renal artery dissection or thrombosis
- Aortic dissections with compromise to renal ostium
- Page kidney (i.e., post-traumatic perirenal fibrosis)
- Metastatic tumor compressing renal parenchyma
- Pheochromocytoma compressing renal artery
- Phakomatosis pigmentovascularis type II b
- Neurofibromatosis
- Behçet’s disease
- Covering of origin of renal artery by aortic stent graft
- Renal artery spasm

“One-Kidney Hypertension” (implies that the entire renal mass is beyond the vascular lesion, either bilateral disease or a solitary functioning kidney)

- Stenosis to solitary kidney
- Bilateral arterial stenosis
- Coarctation of the aorta
- Vasculitis involving renal arteries
- Congenital vascular anomalies
- Atheroembolic renal disease

Figure 37.1 Renovascular Hypertension: Classification. Examples of renovascular disease with associated renovascular hypertension or ischemic renal disease.

4/1000, with a lower prevalence of cerebrovascular involvement of 1/1000.⁴ Data from screening angiography in potential kidney donors suggest that the prevalence may be higher, with FMD observed in 3% to 6% of normotensive individuals. FMD is most common among young females and usually presents as early-onset hypertension between the ages of 15 and 50 years. Because FMD is commonly asymptomatic for many years, FMD can be discovered at any age, sometimes as an incidental finding during angiography. Familial FMD occurs in approximately 10% of cases and tends to involve both renal arteries.⁴ It has also been associated with subclinical evidence of carotid flow abnormalities in first-degree relatives, consistent with an autosomal dominant inheritance pattern.⁵ FMD may also complicate other hereditary conditions, such as Ehlers-Danlos and Marfan syndromes (Fig. 37.3B).

Renal arteries are involved with FMD in 65% to 70% of cases, whereas only 25% to 30% of cases involve cerebral arteries. Both sites are involved in approximately 15% of patients. Hence, young patients presenting with spontaneous carotid artery dissection or occlusion should be considered at risk for FMD of the kidney and vice versa.

The molecular etiology of FMD is unknown. Multiple candidate genes have been proposed, but no specific genetic mutations have been identified. These lesions are disruptions of vascular wall components with abnormal deposition of collagen in bands and, in some cases, disruption of elastic membrane. Several subtypes of FMD have been described on the basis of the predominant layers of the arterial wall involved, but these are not mutually exclusive. The three main types of FMD are medial fibroplasia, which is the most common, and intimal and periadventitial fibroplasia.

Figure 37.2 Fibromuscular dysplasia. A, Selective renal arteriogram illustrating the beaded appearance of fibromuscular dysplasia with multiple webs characteristic of medial fibroplasia in a 39-year-old woman. B, Selective injection of the same renal artery after technically successful percutaneous transluminal renal angioplasty. (Courtesy Michael McKusick, MD, Mayo Clinic, Rochester, Minnesota, USA.)

The histologic features coincide with the arteriographic “phenotype” outlined in Figure 37.4. Medial fibroplasia is most common and is manifested as a “string of beads” appearance of alternating stenoses with apparent luminal dilations. Other lesions appear as focal or elongated vascular narrowing, sometimes with diffuse attenuation of branch or distal vessels. Unlike ASRVD, FMD generally appears in the middle or distal

Clinical Manifestations and Disorders Associated with Fibromuscular Dysplasia

Clinical Manifestations
Incidental finding (e.g., living kidney donors)
Renovascular hypertension
Renal infarction
Loin or flank pain
Hematuria
Retroperitoneal hemorrhage
Cerebrovascular accident
Disorders
Tuberous sclerosis
Marfan syndrome
Ehler's-Danlos syndrome
Cystic medial necrosis
Coarctation of the aorta
Alport's syndrome
Renal agenesis or dysgenesis
α 1-Antitrypsin deficiency
Medullary sponge kidney
Pheochromocytoma
Infantile myofibromatosis
Ergotamine preparation, methysergide
Cigarette smoking
Collagen III glomerulopathy
Atherosclerotic renovascular disease

Figure 37.3 Clinical manifestations and disorders associated with fibromuscular dysplasia.

portions of the renal artery or branch vessels. Renal artery aneurysms occur in up to 50% of cases of FMD and can cause vessel occlusion or dissection. Arteriovenous fistulas and thrombosis can also occur.

Atherosclerotic Renovascular Disease

Atherosclerotic narrowing of the renal arteries generally occurs in older patients (>50 years of age) and is associated with systemic atherosclerosis. Younger patients with premature atherosclerosis are also at risk. ASRVD is the most common cause of RVH and can contribute to loss of renal function leading to end-stage renal disease (ESRD) (Fig. 37.5). Atherosclerotic plaque often arises in the first or second centimeter of the renal artery or may extend from the aorta into the renal ostium. Aortic and renal vascular calcification is often present. ASRVD is a manifestation of systemic atherosclerotic disease and is associated with coronary, cerebrovascular, peripheral vascular, and aortic disease.⁶ The prevalence of ASRVD appears to be increasing. This probably reflects the fact that more people are surviving to ages when atherosclerotic vascular disease in the visceral abdominal vessels can reach critical levels, producing RVH when the kidney is affected. In patients undergoing angiography of the peripheral or coronary circulation, ASRVD is found in 11% to 42%.⁷ Predictors of ASRVD include a history of hypertension, presence of renal functional impairment, coexisting vascular or coronary artery disease, presence of abdominal bruits, and history of smoking. Renal artery lesions are bilateral in 20% to 40% of such patients.

Estimates of the prevalence of ASRVD depend on the population screened. One population-based study of a cohort of 870 patients older than 65 years screened with renal artery duplex sonography found a 6.8% prevalence of ASRVD, defined as greater than 60% stenosis. No differences were detected between African Americans and Caucasians.⁸ Autopsy series report an overall prevalence of 4% to 20%, with progressively higher rates

Histologic Classifications of Fibromuscular Dysplasia and Angiographic Phenotypes

Type	Frequency	Histology	Angiographic Appearance
Medial			
Medial fibroplasia	85%-100% most common	Alternating ridges of collagen /loss of elastic membrane	"String of beads" Medial: bead diameter is larger than lumen diameter Perimedial: bead diameter is smaller than lumen diameter
Perimedial fibroplasia	Rarer (10%–15%)		
Medial hyperplasia	Rarest	True smooth muscle hyperplasia: no fibrosis	Medial hyperplasia: smooth stenosis without beads
Intimal	<10%	Circumferential deposition of collagen in intima: fragmented or duplicated internal elastic lamina	Concentric smooth stenosis: long smooth narrowing
Adventitial	<1%	Dense collagen replaces fibrous tissue in adventitia and surrounding tissue	Smooth stenosis or diffuse attenuation of vessel lumen

for those older than 60 years (25% to 30%) and 75 years (40% to 60%). These studies suggest that ASRVD leading to renal artery stenosis is the single most common cause of secondary hypertension in patients older than 50 years. It is also commonly a resistant form of hypertension and can be associated with systolic hypertension with wide pulse pressures. Furthermore, renal artery stenosis from ASRVD has been reported to contribute to the decline in renal function in 15% to 22% of patients reaching ESRD.

PATHOPHYSIOLOGY

Renovascular occlusive disease from any cause can activate pressor pathways that tend to restore renal artery perfusion

pressures. Most notable among these is activation of the renin-angiotensin-aldosterone system (RAS). Activation of plasma renin occurs only after poststenotic pressures fall by at least 10% to 20% compared with aortic pressures.⁹ Luminal occlusion of less than 60% (cross-sectional area) rarely produces any measurable decrements in either pressure or flow. Hence, a fall in renal perfusion pressure sufficient to initiate RVH occurs only when luminal occlusion is relatively severe, usually in the 70% to 80% cross-sectional occlusion range (Fig. 37.6).

When critical stenosis develops and reduces renal perfusion pressure, multiple mechanisms are activated in the kidney to restore renal blood flow. Central to this process is the release of renin from the juxtaglomerular apparatus, leading to activation of the RAS. This is mediated in part by stimulation of neuronal

Figure 37.6 Hemodynamic effects of stenotic lesions. Changes in blood flow and arterial pressure across a carefully quantitated arterial lesion are barely detectable until cross-sectional area diminishes by 75% to 80%. (From reference 10.)

nitric oxide synthase (NOS) and cyclooxygenase 2 in the macula densa. Blockade of the RAS at the time an experimental renal artery lesion is created prevents the development of hypertension. Studies in transgenic mice without receptors to angiotensin confirm that development of RVH requires an intact RAS.¹¹ In the absence of RAS blockade, systemic arterial pressures increase until renal perfusion is restored. Studies in both experimental models and humans indicate that additional mechanisms contribute to long-term elevation of BP in the presence of renal artery stenosis, including activation of the sympathetic nervous system (SNS), impairment of nitric oxide (NO) generation, and release of endothelin as well as hypertensive microvascular injury to the nonstenosed kidney.¹²

Mechanisms responsible for sustained RVH differ according to whether one or both kidneys are affected by significant stenoses, either pathologically or created in animal models with use of clips (Fig. 37.7). The nomenclature distinguishes between a situation in which one clip is present with a normal contralateral or unclipped kidney (so-called one-clip, two-kidney hypertension) and a situation in which the entire renal mass is affected with no contralateral kidney (one-clip, one-kidney hypertension). Both of these situations depend on impaired renal perfusion and initial activation of the RAS with sodium retention. However, the presence of a normal contralateral kidney allows pressure natriuresis to occur (see Chapter 2), in which the elevated perfusion pressure mediates natriuresis in the nonstenotic kidney. Because the nonstenotic kidney functions to eliminate the excess sodium, the level of perfusion to the stenotic side remains reduced, leading to sustained activation of the renal artery stenosis. This sequence of events producing angiotensin II (Ang II)-dependent hypertension and secondary aldosterone excess with hypokalemia is summarized in Figure 37.7.

By contrast, one-clip, one-kidney hypertension represents a model in which the entire renal mass is exposed to reduced pressures beyond a stenosis. There is no normal or nonstenotic kidney to counteract increased systemic pressures. As a result, sodium is retained and blood volume expanded, which eventually feeds back to inhibit the RAS (Fig. 37.7B). Therefore, one-clip, one-kidney hypertension is typically not angiotensin dependent

unless removal of volume is achieved that reduces renal perfusion pressure and activates the RAS.

The fundamental differences between these forms of RVH have clinical implications. Many diagnostic studies used to evaluate the functional significance of renal artery lesions depend on comparisons of the different physiologic response of the two kidneys, which may give a false impression if both kidneys are involved. Furthermore, diagnostic tests that depend on differences in responses to alterations in sodium status (such as measurement of renal vein renin levels after sodium depletion or individual kidney sodium reabsorption) may be problematic, as high levels of Ang II and aldosterone stimulate sodium reabsorption in both the stenotic and nonstenotic kidney. This accounts in part for the less frequent use of such tests in recent years.

Variations in the natural history of RVH complicate understanding of primary pathogenic mechanisms. Rarely is it known exactly when critical levels of stenosis develop. In experimental models, the relative importance of pressor mechanisms, including measurable activation of the RAS, changes with time. Levels of circulating plasma renin activity decrease, as does the responsiveness of BP to short-term blockade of the renin system. Several mechanisms have been proposed to explain such changes, including a slowly developing pressor action of Ang II, a transition to alternative pressor mechanisms, and intrinsic renal injury to the nonstenotic kidney, which ultimately sustains hypertension despite reversal of the vascular lesion. In experimental models, this translates into a time limit for reversibility of RVH.

There are several clinical correlates of variable time course. First, it is not known how best to identify when revascularization will fail to improve BP control, although a brief duration of hypertension suggests a more favorable response to intervention. As a result, many of the diagnostic studies that depend on lateralization of effects have only modest predictive value when results are negative. As a general rule, they are most reliable when results are positive, meaning that high-grade lateralization accurately predicts improvement after revascularization. A negative test result, however, may also be associated with a beneficial outcome. Second, coexistent intrarenal disease, such as arterio-sclerosis with glomerulosclerosis, is usually associated with persistent hypertension despite correction of renal artery

Figure 37.7 Pathogenesis of renovascular hypertension in one-kidney versus two-kidney model. **A**, In unilateral stenosis with two kidneys, opposing forces between the stenotic kidney, which has reduced perfusion pressures, and the nonstenotic contralateral kidney, which has increased perfusion pressures, result in laboratory and clinical features of angiotensin-dependent hypertension. **B**, In unilateral stenosis with a solitary functioning kidney or in a patient with bilateral critical renal artery stenosis, reduced perfusion pressure to the stenotic kidney in the absence of a normal kidney excreting sodium leads to sodium and volume retention, ultimately associated with hypertension without persistent activation of the RAS.

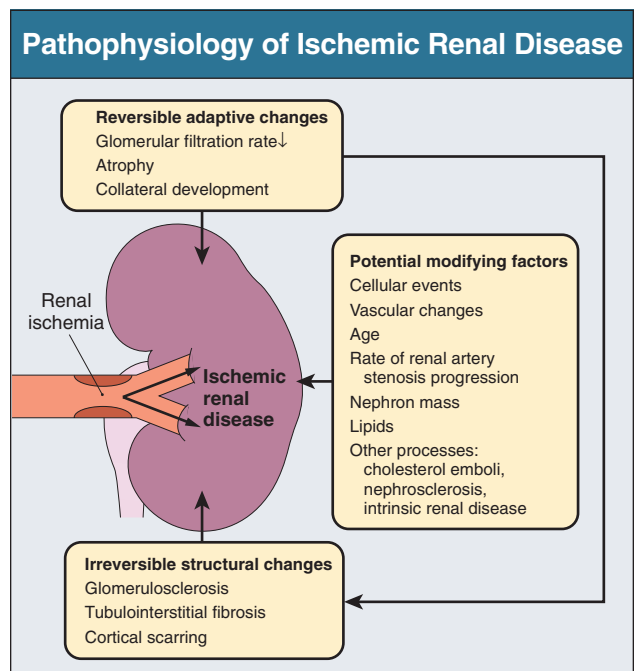

Figure 37.8 Pathophysiology of ischemic renal disease. Chronic ischemia of the kidney is associated with reversible functional involution and atrophy as well as with irreversible structural changes. A number of external factors influence the renal response to chronic ischemia. (Modified from reference 14.)

stenosis, particularly for patients with ASRVD.¹³ In these patients, a long duration of hypertension allows the development of arteriolosclerotic lesions and renal injury in the contralateral kidney (Fig. 37.7A). Thus, older age and a long duration of hypertension, for example, more than 3 to 5 years, predict a poorer outcome of intervention in this population of patients. Most of these elderly patients with ASRVD also have impaired renal function related to the renal injury in addition to main renal artery stenosis.

Relationship to Ischemic Renal Disease

Activation of pressor mechanisms producing RVH can occur without loss of renal size or function. However, the more common clinical scenario involves both increasing severity of hypertension and deteriorating renal function, often with loss of renal size. Hence, the decision to consider renal revascularization most commonly combines consideration of both the likelihood of salvage or preservation of function and the benefits regarding BP control. Mechanisms underlying parenchymal renal damage may differ from those responsible for generating hypertension. Improved BP control after revascularization sometimes may be achieved without appreciable improvement in kidney function.

The sequence of events underlying the transition from “reversible” loss of function beyond a vascular lesion to “irreversible” tissue fibrosis is not well understood. Renal blood flow differs from many other organs in being vastly greater than needed for metabolic needs alone. Basal energy requirements are met with less than 10% of blood flow, consistent with its filtration function. Nonetheless, reduced renal perfusion activates multiple mechanisms of tissue injury. A general scheme by which vasoactive and inflammatory pathways are activated is summarized in Figure 37.8. Atherosclerotic and inflammatory pathways

sometimes lead to arteriolar disease, often with abnormal endothelial function that may parallel tissue injury and accelerate cytokine signaling pathways.¹⁵ At some phase, microvascular rarefaction occurs that accompanies a fall in tissue oxygenation and activation of fibrogenic pathways.¹⁶ Irreversible loss of viable microcirculation may explain some of the limitations observed after restoration of large-vessel patency (e.g., with renal revascularization).

Activation of the RAS and endothelial systems, such as endothelin and oxidative stress pathways, has been demonstrated with renal artery stenosis models.¹⁵ These systems are known to modulate both inflammatory and fibrogenic pathways that lead to tissue scarring. The term “ischemic” renal disease is speculative; studies of renal vein oxygen levels and erythropoietin (EPO) secretion do not support the premise of whole-kidney oxygen deprivation. Measurements of cortical and medullary deoxyhemoglobin by use of blood oxygen level-dependent magnetic resonance (MR) in most patients with renal arterial disease fail to demonstrate oxygen desaturation under most chronic conditions.¹⁷ Medullary oxygen levels are normally substantially lower than those in the cortex and are heavily dependent on the level of solute transport. Under acute conditions of reduced blood flow with persistent filtration and tubular function, levels of deoxygenated hemoglobin representing medullary ischemia rise.¹⁸

At some level of sustained vascular occlusion, pathways of cytokine and cell signaling activate tissue fibrogenesis and breakdown of intact tubular structures. Glomeruli are usually well preserved, although collapsed.

Sodium Retention and Flash Pulmonary Edema

Some subjects with bilateral renal artery stenosis will develop severe hypertension and extracellular fluid volume excess due to impaired pressure natriuresis. Under such conditions, there can be the sudden (“flash”) onset of pulmonary edema in association with rapid development of circulatory congestion. Diuresis can result in exaggerated swings in BP, circulatory congestion, and renal function.¹⁹ Case series suggest that renal revascularization can facilitate fluid volume management, reduce hospitalization, and occasionally improve cardiac function independent of interventional procedures for the heart itself.²⁰

CLINICAL MANIFESTATIONS

Renovascular Hypertension

In the 1970s, a cooperative study of RVH compared clinical characteristics of patients with surgically proven RVH with those of patients with primary hypertension. Some of these were statistically more prevalent in RVH, such as the presence of an abdominal bruit, hypokalemia, and absence of a family history of hypertension. Recent studies suggest that for any level of blood pressure, patients with RVH may have higher nocturnal pressures (nondipper) and have more severe target organ manifestations, including left ventricular hypertrophy (Fig. 37.9).²¹ Series of individuals with treatment-resistant hypertension indicate that elevated cholesterol, impaired renal function, lower body mass index (BMI), and smoking offer positive clues. In practical terms, none of these features is sufficiently sensitive or specific to offer diagnostic precision. Recent reports indicate that RVH rarely may be associated with nephrotic-range proteinuria, which can regress with correction of the vascular lesions.²²

Clinical Manifestations of Renovascular Hypertension

Features of Renovascular Hypertension

- Activation of renin-angiotensin-aldosterone system (RAS) - early
- Paroxysmal symptoms: sympathetic nervous system activation
- Abnormal circadian rhythm: loss of nocturnal pressure fall
- Accelerated target organ damage
 - Left ventricular hypertrophy
 - Microvascular disease
 - Renal injury: fibrosis

Clinical Syndromes Associated with Atherosclerotic Renal Artery Stenosis

- “Incidental lesion”: no hemodynamic effect
- Renovascular hypertension (see above)
 - New-onset hypertension
 - Acceleration in previously hypertensive patient
- Acute renal dysfunction
 - ACE or ARB-induced acute renal failure
 - Acute or chronic renal insufficiency
- Unexplained chronic kidney disease: especially in the elderly
- Circulatory congestion: “flash pulmonary edema”

Figure 37.9 Clinical manifestations of renovascular hypertension. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker.

Blood pressure elevations from RVH vary widely. Acute renal artery occlusion may only gradually produce an increase in pressure or it may produce a rapid increase in hypertension that may precipitate a hypertensive urgency or emergency (see Chapter 36). Before the current era of antihypertensive agents, 30% of Caucasian patients appearing in an emergency department with hypertensive urgency (defined as grade III or IV hypertensive retinopathy) were ultimately found to have RVH. Syndromes of polydipsia and accelerated hypertension with hyponatremia and hypokalemia, sometimes attributed to the dipsogenic actions of Ang II, also have been observed.

Current antihypertensive medications have changed the clinical presentation of RVH. Recent consensus documents emphasize the need for effective population-wide BP control while limiting the number and expense of diagnostic studies. As a result, most patients with hypertension simply are treated and subjected to few laboratory investigations. For those who reach acceptable BP control without adverse effects, no further studies are performed. Hence, many if not most cases of true RVH are not detected (Fig. 37.10) unless hypertension becomes more difficult to treat or renal dysfunction ensues.

An additional reason that RVH is less frequently detected is the availability of orally active antihypertensive agents that block the RAS. Early studies beginning with captopril indicated that satisfactory BP control can be achieved in more than 86% of patients with RVH compared with less than 50% with previously available drugs. In recent years, widespread application of angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) for indications other than hypertension, for example, congestive cardiac failure, diabetic nephropathy, and other proteinuric renal diseases, increases the exposure of individuals with undetected renal artery stenosis to these drugs.²³

One result of these changes has been the emergence of distinctive clinical syndromes that merit evaluation in patients at

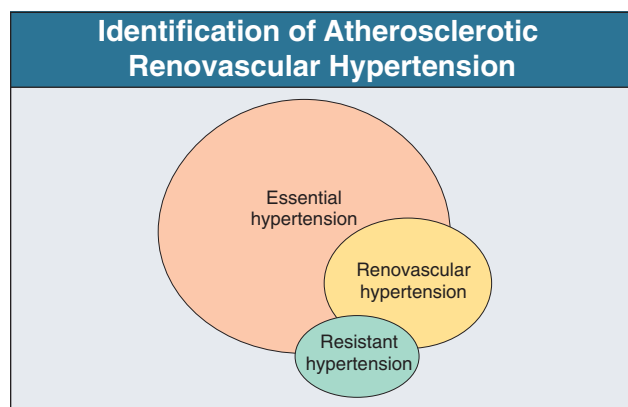

Figure 37.10 Identification of atherosclerotic renovascular hypertension. Venn diagram indicates that many patients with renovascular hypertension are indistinguishable from patients with primary hypertension. A subset develops problematic or resistant hypertension, which brings them to clinical attention and consideration for renal revascularization.

risk for ASRVD (see Fig. 37.9). As a result, patients who typically undergo diagnostic evaluation and renal revascularization are a subset of the population of patients with RVH. This subset is characterized generally by more severe hypertension, decreasing renal function, propensity for rapid volume accumulation manifested as flash pulmonary edema, and, occasionally, advanced renal failure.

Ischemic Renal Disease

The diagnosis of IRD should be considered in several clinical settings as summarized in Figure 37.9.

Renal Impairment in Patients with Renovascular Hypertension or in the Atherosclerotic Age Range

IRD should be excluded in the atherosclerotic age group, particularly when other vascular disease is detected. Many but not all will have a history of hypertension. It remains difficult to separate primary vascular disease from renal parenchymal injury associated with nephrosclerosis from other vascular insults. Clues to IRD include asymmetry of renal size and recent deterioration of renal function, as opposed to slowly progressive CKD. An asymmetrically small kidney in an adult older than 50 years has a 70% chance of being associated with ipsilateral renal artery stenosis.

The development of renal impairment in patients treated medically for long-standing hypertension should raise suspicion for possible IRD. Given the high frequency of bilateral renal artery stenosis (between 30% and 50%), the possibility of IRD should always be considered in patients with known prior RVH. The most common presentation of atherosclerotic renal artery stenosis is unilateral involvement in a patient with CKD associated with long-standing hypertension. In this instance, renal impairment cannot be attributed solely to IRD because the renal artery stenosis affects only one kidney. The kidney supplied by the stenotic vessel may be ischemic, resulting in diminished GFR, RVH, and atrophy. The contralateral kidney with the patent renal vessel often hypertrophies and compensates with hyperfiltration. However, over time, this kidney develops parenchymal injury. Much of the time, the kidney with the patent renal artery has worse renal function than the poststenotic kidney.²⁴

Acute Kidney Injury After Starting of Antihypertensive Medications or RAS Blockade

Patients with hemodynamically significant renal artery stenosis to the entire functioning nephron mass are at risk for the development of “functional” acute kidney injury (AKI) after institution of ACE inhibitors or ARBs. The sudden reduction in systemic BP, in the setting of critical renal artery stenosis, may reduce renal artery pressure below the levels needed to sustain glomerular filtration by autoregulation, estimated to be about 60 mm Hg. This can occur with reduction in BP by any antihypertensive agent. With medications that block the production or action of Ang II, alterations in glomerular hemodynamics may result in acute worsening in GFR that is independent of effects on systemic blood pressure.²⁵ Normally, activation of Ang II causes efferent arteriolar vasoconstriction, which preserves transcapillary filtration pressures at the glomerulus when glomerular pressures are reduced, thereby maintaining GFR. The loss of this compensatory mechanism induced by agents that inhibit or block the RAS can result in functional AKI. This typically occurs within a few days from the start of antihypertensive therapy and is usually but not always reversible.

Most patients with renal vascular disease who are treated with ACE inhibitors or ARBs do not develop AKI. This probably reflects minimal dependence on Ang II because those with unilateral stenosis have preserved function in the nonstenosed kidney and those with bilateral renovascular disease often have sodium retention that suppresses the RAS. ACE inhibitors and ARBs are more likely to precipitate renal failure in patients with bilateral renal vascular disease if the patients are volume depleted or taking diuretics, producing circumstances that increase Ang II dependence of the GFR. Conversely, AKI can occur with the use of ACE inhibitors without IRD. This most commonly occurs in patients with cardiac or hepatic dysfunction or in patients with intravascular volume depletion because, in these settings, GFR is also Ang II dependent. For this reason, it is imperative to recheck kidney function within 2 weeks of institution of therapy with medications that block the RAS.²⁶ In a prospective study, the observation of 20% increase in serum creatinine or more after administration of an ACE inhibitor detected most cases of bilateral severe renal artery stenosis.²⁷

Flash Pulmonary Edema

IRD may present as recurrent episodes of flash pulmonary edema. These episodes can be unpredictable, sudden, and life-threatening and may be associated with low, normal, or very high BP at the time of presentation. Renal revascularization can reverse the cyclical flash pulmonary edema and improve pulmonary function even in those patients with poor preoperative cardiopulmonary status.²⁸ In one series, 41% of subjects with bilateral renal artery stenosis had a history of pulmonary edema compared with 12% with unilateral renovascular disease. Seventy-seven percent of the patients with bilateral renal artery stenosis had no further pulmonary edema after renal artery stent placement in one or both arteries. The patients who did have recurrent pulmonary edema all had evidence of stent thrombosis or restenosis.²⁹ The mechanisms of pulmonary edema reflect combinations of diastolic or systolic ventricular dysfunction occurring in association with chronic reduction in GFR and sodium retention. These may coincide with superimposed episodes of severe hypertension or further increases in sodium retention. There are no prospective clinical studies specifically examining the effect of optimal medical therapy for BP and volume status on the frequency of events in these patients. Initial

reports from prospective, randomized clinical studies, such as the Angioplasty and Stenting for Renal Artery Lesions (ASTRAL) study, demonstrated no differences in hospitalizations or episodes of congestive heart failure (CHF) in intensively treated subjects with or without renal artery stenting.³⁰

Acute Oligoanuric Renal Failure Superimposed on Chronic Kidney Disease

Patients with high-grade renal artery stenosis are at risk for renal artery occlusion. When renal artery stenosis is bilateral or unilateral in the setting of a single functioning kidney, progression to total occlusion can present as oligoanuric acute renal failure, sometimes associated with a hypertensive emergency. A clinical clue to this diagnosis is abrupt-onset oligoanuria. In this setting, the kidney parenchyma may be viable despite lack of filtration; in some patients, collateral vessels maintain renal viability in the face of proximal renal artery occlusion. Clues to renal viability include preserved renal length and evidence of renal contrast enhancement (“renal blush”) seen on delayed or venous-phase images during renal angiography. When these factors are present and the clinical course is consistent with recent occlusion, there is a chance of retrieval of renal function if revascularization is feasible clinically and anatomically. In this setting, urgent vascular surgical consultation should be sought, and it should be assumed that the kidneys may be viable for weeks to months.

Incidental Renal Artery Stenosis

As mentioned, ASRVD is highly correlated with disease in both the coronary and peripheral vasculature. It is commonly identified incidentally at the time of angiography or computed tomographic (CT) imaging for other indications. Most of these patients with coexisting ASRVD and coronary artery disease have only moderate degrees of renal artery stenosis (50% to 75%) of minimal hemodynamic impact. The use of screening renal aortography at the time of coronary angiography has been proposed for some situations. Whereas the addition of aortography to the coronary procedure adds only minimal risk, it does incur expense. One follow-up study of patients with incidentally detected renal artery lesions during coronary angiography found that the presence of renal artery lesions is an independent risk factor for mortality, which may reach 30% during 4 years in high-risk groups.³¹ This does not mean, however, that revascularization of renal artery stenosis in these patients reverses this risk. Indeed, renal artery revascularization for such patients should be reserved for those with firm indications for intervention.

NATURAL HISTORY

Disease Progression

The risk of progressive vascular occlusion is a central issue in management of renovascular disease. As well as the risk of progressive renal atrophy and progression to advanced kidney failure, there are also associated risks for cardiovascular events. The natural history of fibromuscular disease differs from that of ASRVD.

Fibromuscular Dysplasia

The natural history of FMD is variable, but angiographic progression can occur. This can be manifested as the development of new focal lesions within the same arterial bed, worsening arterial luminal diameter narrowing within a specific lesion,

involvement of a new vascular territory, or development of arteriovenous fistulas or aneurysms or enlargement of existing ones. Most studies of the natural history of FMD show a decline in progression with age, with few patients developing new or progressive lesions after the age of 50 years. From a renal standpoint, FMD rarely causes ischemic renal failure, but the attendant hypertension can be associated with renal cortical atrophy.³² FMD can also rarely lead to thrombosis or dissection of the renal vessel with renal infarction.

Atherosclerotic Renal Artery Stenosis

The natural history of atherosclerotic renal artery stenosis includes risk for progressive vascular occlusion that clinically translates into stability of BP control, kidney size and function, and cardiovascular risk. Retrospective serial angiographic studies (1980s) suggested that renal artery stenosis commonly progresses during a 2- to 5-year period. Progression is usually defined as a greater than 25% luminal diameter narrowing or progression from severe stenosis to vascular occlusion. During a 4- to 5-year period, between 6% and 16% of stenoses proceed to occlusion. Prospective studies between 1990 and 1997 using Doppler ultrasound in patients with atherosclerotic renal artery lesions indicated that hemodynamic progression overall approaches 31% during 3 years, varying by the degree of initial stenosis. In this series, only nine of 295 vessels (3%) resulted in total occlusion.³³ Measurable loss of renal length (more than 1 cm) is less common but accompanies progressive vascular occlusion. Changes in serum creatinine concentration are often minimal.³⁴

The predictors of progressive disease relate primarily to the degree of initial stenosis, being most likely in those with more than 60% stenosis. Progressive renovascular disease often occurs without changes in BP control. Dyslipidemias associated with atherosclerosis have not been shown to be independent predictors of progression. However, therapy with statins appears to reduce the risk of progression and even to induce regression of atherosclerotic renal artery stenosis.³⁵ Statins also appear to attenuate renal parenchymal injury associated with experimental ASRVD.³⁶

Follow-up studies of patients with incidentally detected, high-grade renal artery stenosis (>70%) treated medically indicate that less than 10% required later revascularization for intractable hypertension.³⁷ Another report noted that few patients with incidental renal artery stenosis progressed to ESRD during a follow-up period between 8 and 9 years.³⁸ In patients observed after simultaneous renal angiography at the time of cardiac catheterization, no difference in serum creatinine concentration was noted between those with and those without renal artery stenosis at follow-up.

Mortality

ASRVD and IRD are associated with limited long-term survival, consistent with widespread atherosclerotic disease. Recent retrospective analyses report 3- to 5-year mortality rates between 30% and 35% in patients with renal artery stenosis largely due to cardiovascular events or stroke. In follow-up of a large cohort of more than 1200 patients who underwent coronary and renal angiography, patients with renal artery stenosis were found to have a 65% 4-year survival rate versus 85% for those without renal artery stenosis at the time of catheterization. Five- and 10-year survival rates for patients reaching ESRD due to IRD are as low as 18% and 5%, respectively.³⁹

Relative Value of Imaging Methods for Evaluating the Renal Vasculature					
Methods	Images of Vessels	Tissue Perfusion	Function (GFR)	Advantages	Disadvantages
Spiral computed tomographic angiography	+++	+	±	Provision of three types of images, examination of venous structures, might be useful for evaluating transplant donors	High contrast requirement
Contrast angiography	+++	++	±	Nephrography estimates volume of viable tissue; gold standard	Risk of catheter-induced injuries and contrast nephropathy
Captopril renography	—	+++	++	Change in GFR might estimate reversibility of the lesion; widely available, noninvasive; totally normal renogram effectively excludes significant vascular disease	
Duplex ultrasonography	++	++	—	Precise measurement of flow velocity, suitable for serial studies, relatively inexpensive	Produces little functional information; is not suitable for accessory vessels
Magnetic resonance angiography	++	++	±	No radiation exposure	Gadolinium contrast not used for eGFR <30ml/mg concern for nephrogenic systemic fibrosis

Figure 37.11 Relative value of imaging methods for evaluating the renal vasculature. The available techniques vary in their ability to image the renal vessels, to assess tissue perfusion, and to measure glomerular filtration rate (GFR).

Whether renal revascularization improves survival in atherosclerotic renal artery stenosis is controversial.⁴⁰ In one study, those patients with bilateral ASRVD who were treated medically actually had better follow-up renal function than did those who had undergone revascularization, and there was no difference in survival.⁴¹ However, other studies suggest that intervention directed at improving renal function may improve survival in this group of patients with diffuse atherosclerotic disease. Watson and colleagues⁴² reported 2-year survival rates of 80% among patients with ischemic nephropathy who underwent endovascular stenting. Yet, the increased mortality risk of worsening renal function complicating endovascular interventions has to be considered in the risk-benefit analysis of interventions.⁴³ Randomized trials currently in progress are addressing whether intervention confers quality of life and mortality benefit from interventions or medical therapy alone.

DIAGNOSIS

Several screening laboratory tests have been proposed over the years to identify patients with RVH. Some of these depend on identifying activation of the RAS, such as renin-sodium profiling, and many depend on side-to-side comparisons of kidneys, assuming that one kidney is unaffected. Under the best of circumstances, these studies are rarely more than 80% sensitive or specific. As a result, their value as predictors depends greatly on the pretest probability of renovascular disease.¹³ Furthermore, functional tests related to activation of the RAS depend heavily on the test conditions, including sodium intake and concurrent antihypertensive medications, many of which affect levels of plasma renin activity. As a result, many clinicians no longer use these tests extensively.

Diagnosis of RVH requires demonstration of a critical stenotic vascular lesion affecting the renal artery. Conventional angiography remains the reference standard to define the anatomy of the renal vasculature, but it is usually performed only after a less invasive procedure has increased the level of probab-

ity that such a lesion is present. Angiography is often performed at the same procedure with an endovascular intervention such as angioplasty with or without stenting. Several characteristics of commonly used noninvasive imaging procedures are summarized in Figure 37.11.

The goal of noninvasive testing is to allow the physician to limit further invasive testing. The most commonly employed noninvasive vascular studies include nuclear renal scan (usually captopril- or enalapril-enhanced renography), renal artery duplex ultrasonography, CT angiography, and magnetic resonance angiography (MRA) (see Chapter 5). These methods provide different information and may vary between institutions as regards both availability and reliability. Figure 37.12 illustrates an example of a captopril-enhanced renogram in a patient with renal artery stenosis. This examination provides no direct image of the renal vessel but does provide a view of the rate of isotope appearance and washout, reflecting the sequence of renal blood flow and filtration. The study provides functional information about the size and excretory capacity of the kidney as well as emphasizing the role of Ang II in maintaining GFR. This test has a high negative predictive value when it is completely normal. Several studies suggest that a completely normal captopril renogram effectively excludes hemodynamically significant renal artery stenosis.⁴⁴ The fact that many intrinsic renal abnormalities unrelated to the main renal artery may change these curves limits its value in the presence of reduced GFR (serum creatinine concentration >2.0 mg/dl or 176 μ mol/l).

Renal artery duplex scanning is applied widely to identify and to follow hemodynamic effects of vascular lesions serially. It is relatively inexpensive and requires no administration of contrast material. It is most effective in detecting lesions of the main renal artery near the ostium, making it a better screening test for ASRVD than for FMD. However, the reliability of this method depends on the skill and patience of the ultrasonographer and on the body habitus of the patient. Duplex ultrasound provides little functional information about the kidney beyond the vascular lesion, although many important structural features, including the size of the kidney and presence

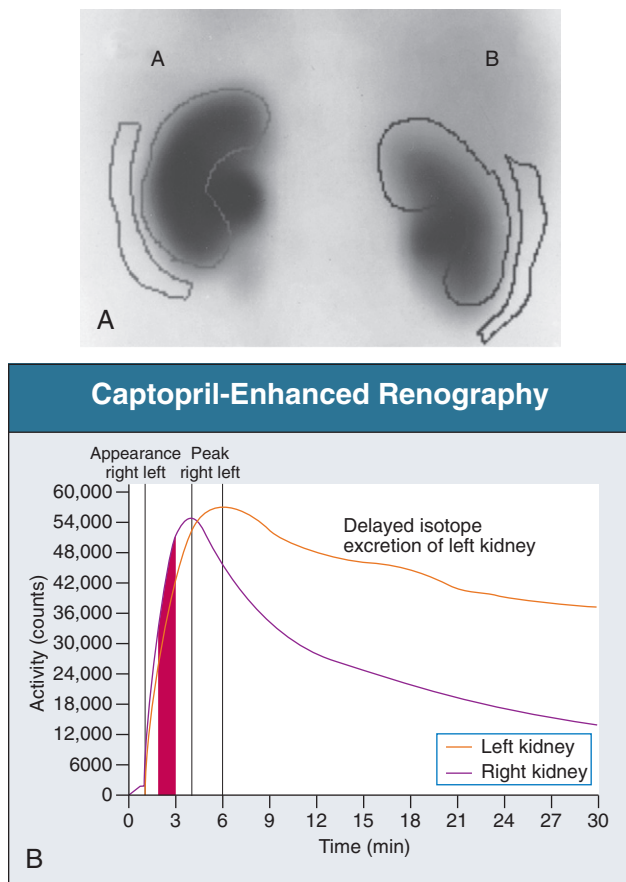

Figure 37.12 Captopril-enhanced renography. **A**, Scan in a patient with newly developing hypertension. **B**, Renogram demonstrates delayed arrival and excretion of isotope (MAG3) in the affected left kidney.

of ureteral obstruction, may be determined. The diagnostic criteria for hemodynamically significant renal artery stenosis by duplex sonography include acceleration of blood flow through the area of stenosis that exceeds that in the aorta and abnormal waveforms representing blood flow in the affected vessel (see Chapter 5).

MRA offers the potential to provide both structural vascular imaging and functional information. MRA with gadolinium contrast enhancement gives excellent imaging of the main renal arteries but is now less used because of the association of nephrogenic systemic fibrosis with gadolinium exposure in patients with reduced GFR and ESRD. Other limitations of MRA include interobserver variability, a recognized tendency to overestimate luminal narrowing, and limited sensitivity for mid and distal vascular lesions associated with FMD. Studies are under way to improve the sensitivity and negative predictive value of non-gadolinium-enhanced MRA in the detection of renal artery stenosis (Fig. 37.13).

CT angiography (CTA) with vascular reconstruction achieves image qualities nearly equivalent to those of angiography but requires more iodinated contrast material. It is becoming the noninvasive study of choice in those patients whose risk of contrast-associated nephrotoxicity is minimal. Yet, CTA also can overestimate the degree of stenosis with an estimated false-positive rate that varies according to reconstruction protocols and regional differences in experience. It is highly sensitive for identification of lesions associated with FMD and is a good

Figure 37.13 Magnetic resonance angiogram with and without gadolinium contrast enhancement. **A**, High-grade stenosis affecting the left inferior renal artery is evident, with functioning kidney tissue as reflected by gadolinium nephrogram (arrow). Concerns about the role of gadolinium in the development of nephrogenic systemic fibrosis have greatly reduced the use of this contrast agent. **B**, As a result, methods to image the vasculature without contrast material are being developed that produce excellent reconstructed images (arrow).

screening test for these patients who generally have good kidney function (Fig. 37.14).⁴⁵

Angiography remains the gold standard for defining the degree of stenosis associated with ASRD and for identification of FMD. Aortography provides important anatomic and functional information in cases of tight stenosis or occlusion, including the demonstration of delayed perfusion of the kidney and distal reconstitution of the proximally occluded renal vessel. This is important in consideration of surgical revascularization for retrieval of renal function. In experienced hands, diagnostic renal arteriography to identify significant renal artery stenosis can be performed with as little as 20 ml of iodinated contrast material. In very high risk cases, carbon dioxide can be used in place of contrast material to assess the renal ostium and proximal vessel, where atherosclerosis commonly develops.

Renal vein renin measurements can be helpful in predicting the BP response to renal revascularization.⁴⁶ Previous studies indicated that lateralization of renal vein levels (a ratio of more than 1.5:1 between stenotic and nonstenotic kidneys) predicts a favorable blood pressure response for more than 90% of patients.

Figure 37.14 Computed tomographic angiogram illustrating a renal artery aneurysm with an area of renal infarction in right kidney. Coronal image **A**, demonstrates area of intact tissue with no blood perfusion within the kidney parenchyma. Image **B**, illustrates reconstructed view with vascular aneurysm (arrow) and minimal flow in the distribution beyond this segment, consistent with nearly total occlusion. This case presented as accelerated renovascular hypertension treated primarily with blockade of the RAS (see text).

Because failure to lateralize also carried a favorable response in nearly half, the negative predictive value is limited. Some clinicians use these measurements to verify the role of a pressor kidney before undertaking nephrectomy.

TREATMENT OF RENOVASCULAR DISEASE

The Joint National Committee (JNC 7) stated goal of hypertension therapy is to reduce morbidity and mortality “by the least intrusive means possible.” In RVH, this entails balancing the risks and benefits of several modalities ranging from medical therapy

to surgical or endovascular repair. Whether renal revascularization improves outcomes in the era of effective medical therapy is currently the subject of several prospective randomized trials, including ASTRAL and the Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL) study in the United States.

Medical Therapy

Most patients with RVH are treated initially with conventional antihypertensive medications (see Chapter 35). Treatment should address modifiable cardiovascular risk factors (promotion of weight loss, smoking cessation) and include low-dose aspirin and control of hyperlipidemia with statin therapy. Current guidelines for BP control recommend target levels below 140/90 mm Hg or below 130/80 mm Hg for patients with CKD, diabetes, or other high risk. Regimens using agents that interfere with the RAS, such as ACE inhibitors, ARBs, and renin inhibitors as well as the dihydropyridine class of calcium channel blockers, allow achievement of target BP levels in most patients. Based on the benefits of blocking of neurohormonal signals associated with accelerated atherosclerotic disease risk, blockade of the RAS is considered fundamental. Successful renal revascularization rarely leads to withdrawal of all antihypertensive medications in the current era. Hence, it may be questioned whether the costs and risks of renal revascularization are warranted for patients whose blood pressures and kidney function are stable on an acceptable regimen of antihypertensive medications.

Adverse Consequences of Medical Therapy

When there is critical renal artery stenosis, reduction of arterial pressure has the potential for reduction of renal blood flow below levels needed to sustain glomerular filtration. Renal artery pressures beyond the stenosis may decrease below those needed for autoregulation of blood flow and GFR, estimated to be 60 mm Hg in humans.²⁵ Such a reduction in blood flow can develop with any antihypertensive drugs, including β -blockers and sodium nitroprusside. Under these circumstances, renal blood flow may decrease such that thrombotic occlusion may develop.

Antihypertensive agents that interrupt the RAS have an important additional effect: they remove the vasoconstrictive action of Ang II at the efferent arteriole. When preglomerular pressures are reduced for any reason, Ang II preserves glomerular transcapillary filtration pressures by constricting the efferent arteriole preferentially. This allows continued urine formation despite marginal blood flow. Removal of Ang II under these conditions can lead to abrupt cessation of glomerular filtration and urine formation. This decrease in filtration produces a syndrome of “functional acute renal insufficiency,” first described clinically with ACE inhibitors.⁴⁷ The decrease in GFR is apparent clinically under conditions in which the entire renal mass is affected, for example, bilateral renal artery stenosis or stenosis to a solitary functioning kidney. These principles are particularly relevant in nephrology because removal of the efferent actions of Ang II and reduction of transcapillary filtration pressure are advantageous in renal diseases characterized by glomerular hypertension, such as diabetic nephropathy.

Whether the overall effects of ACE inhibitors and ARBs on GFR in renovascular hypertensive patients are beneficial or detrimental has been a matter of controversy. Some diagnostic studies to identify functionally important renal artery stenosis employ ACE inhibitors to magnify differences in GFR between kidneys, for example, captopril-enhanced renography and

Guidelines for Limiting Renal Toxicity with ACE Inhibitors	
Recognize predisposing condition	Widespread atherosclerotic disease Associated renal artery stenosis Impaired pretreatment renal function Solitary functioning kidney Activated renin angiotensin system Low sodium intake Diuretic therapy Other volume losses: vomiting, diarrhea Vasodilator administration Low cardiac function: hypotension, hyponatremia Other agents affecting kidney function (e.g., nonsteroidal anti-inflammatory agents)
Monitor effects of initiating ACE inhibitor therapy	Serum creatinine: measure over the first days and at weeks 2 and 4, especially in high-risk patients Elevated serum potassium: withhold potassium supplements, withhold potassium-sparing agents, and use low-potassium diet
Manage volume	Temporarily withhold diuretics Dose titrate both diuretics and ACE inhibitor Liberalize sodium intake/replace volume, consider rechallenge with ACE inhibitor after volume repletion

Figure 37.15 Guidelines for limiting renal toxicity with ACE inhibitors. ACE, angiotensin-converting enzyme.

captopril-stimulated renal vein renin determinations. It may be argued that identifying a decrease in GFR with an ACE inhibitor allows early detection of critical stenotic lesions in time for renal revascularization. Conversely, some have proposed that administration of an ACE inhibitor to patients with renal artery stenosis poses the hazard of a “pharmacologic nephrectomy,” with the potential for inducing irreversible renal parenchymal injury through ischemia.⁴⁸ Although the functional decrease in GFR induced by ACE inhibitors is usually reversible, patients occasionally do not recover renal function. Hence, ACE inhibitors are a double-edged sword in RVH. They have unique properties, allowing more effective BP control than previously possible, but at the same time, this class of medication has the potential for early loss of filtration pressure in patients with critical levels of renal artery stenosis.

Clinical experience with ACE inhibitors is, however, reassuring. Monitoring studies both in clinical use and in large, prospective trials of patients at high risk for undetected renal artery stenosis, such as the trials of CHF, indicate that clinically important loss of GFR is not common. Most of these trials excluded patients with significant renal dysfunction, however. Postmarketing surveys of more than 15,000 prescriptions in the United Kingdom after the release of enalapril indicated few but important adverse experiences. Most often, these occurred in patients with preexisting renal dysfunction who were taking potassium-sparing diuretics and had other known atherosclerotic disease.²⁵ The clinician caring for patients with complex hypertension should recognize both hyperkalemia and increasing creatinine values during treatment with ACE inhibitors or ARBs (Fig. 37.15) as a sign of potentially critical renal artery stenosis, which may dictate alternative therapy or renal revascularization.

Further diagnostic and therapeutic maneuvers may be warranted in patients with resistant hypertension in which BP remains unsatisfactorily controlled despite three drugs or more. As noted previously, these patients are likely to have associated cardiovascular disease and other comorbid risk. Such patients

may benefit from renal revascularization regarding both level of BP control and stabilization of renal function.

Renal Revascularization

Restoration of the renal blood supply is a rational goal of treating hypertension related to renovascular disease. In a young person with FMD, a permanent cure of hypertension is sometimes achieved. Revascularization offers such a patient relief from a lifelong regimen of antihypertensive medications and cardiovascular risk associated with high BP. In practice, however, cures are infrequent. More often, renal revascularization allows improved BP control and stabilization of the kidney circulation.

Percutaneous Transluminal Renal Angioplasty and Stenting

Fibromuscular Dysplasia The current standard of care in most centers for treatment of hypertension associated with FMD is percutaneous transluminal renal angioplasty (PTRA). Approximately 75% of patients require less antihypertensive medication after technically successful PTRA. Complete cure, defined as normal arterial pressure without medications, is uncommon but can occur. Predictors of hypertensive response include lower levels of preintervention systolic BP, younger age of the patient, shorter duration of hypertension, and positive result of simplified captopril test.⁴⁹ Figure 37.16 summarizes 17 reported series assessing technical success and clinical effect of PTRA in patients with RVH due to FMD.⁵⁰ Although primary technical success rates for PTRA are high (>90%) for FMD, clinicians need to be aware of the potential for restenosis due to either inadequate initial treatment or recurrent fibrosis. This can be treated by repeated PTRA if needed.

When FMD is associated with large aneurysmal dilations exceeding 1.5 cm in diameter, surgical revascularization has been the standard of care. Recent reports indicate that endovascular management of renal artery aneurysms sometimes can

be achieved by use of “covered” stent grafts to exclude the aneurysm.

Atherosclerotic Disease: Endovascular Stents Primary endovascular renal artery stenting has become standard for the interventional treatment of atherosclerotic renal artery stenosis in most centers. Comparisons between PTRAs alone and PTRAs with stent placement establish superior immediate and long-term results with stents.⁵³ With current techniques, target vessel patency rates regularly exceed 95%. Some centers use platelet inhibitors (e.g., clopidogrel) for several months, although the benefits of this approach are unproven.

Functional changes and BP changes may develop during weeks and months, when antihypertensive medications can be adjusted. A rise in BP should raise the question of vessel restenosis, which occurs in between 14% and 30% of subjects during the first year. Most occur within 6 months of revascularization and are more common for smaller vessels.

Figure 37.17 summarizes results from observational reports of more than 1000 patients undergoing renal artery stent placement for either hypertension or renal function preservation. BP control rates were improved in 50%, with 68% of patients experiencing “stabilization” or “improvement” in renal function during a mean of 17 months.⁵⁴ The effects of renal artery stenting on the course of renal impairment in patients with renal artery stenosis remain ambiguous. In nearly all studies reporting renal function outcome after stenting, the percentage of patients experiencing improvement in renal function is offset by a group with worsening renal function. Those whose renal function improves the most tend to be those whose renal function was actively deteriorating during the preceding year.⁵⁵ Patients with deterioration of renal function after stenting likely experience complications such as cholesterol embolization or contrast nephropathy.

Diabetic patients form an important subgroup of those with IRD. Surgical revascularization in this group is associated with similar renal functional responses but an inferior rate of BP responses and a higher postoperative risk for death or eventual dialysis dependence.

Complications Reviews of PTRAs and stenting vary widely regarding the incidence of minor and major complications. Common complications are shown in Figure 37.18 and include contrast nephrotoxicity, which is usually reversible, and atheroembolism, from which patients commonly do not recover. Recent reviews suggest that between 7.5% and 9% of individuals have a major complication related to the procedure.⁵⁴ These include local arterial dissection, aortic dissection, and segmental renal infarction.

Surgical Revascularization

Before the introduction of PTRAs with stents, surgical revascularization was the standard treatment of RVH and IRD. A summary of results of surgical revascularization for RVH is shown in Figure 37.19. Such procedures involve major vascular surgery and carry considerable risk, cost, and morbidity. Risks are reduced with preoperative screening and treatment of associated coronary and carotid disease. As a result, surgical intervention for renovascular disease now is reserved for patients refractory to medical therapy, for whom endovascular therapy fails or does not offer adequate therapy for associated aortic disease.⁵⁶ Despite these caveats, successful surgical revascularization in well-selected cases provides durable restoration of kidney blood supply and long-term survival (81% at 5 years).⁵⁷

Some patients with IRD who are dialysis dependent experience recovery of renal function after surgical revascularization.⁵⁹ The best predictor of successful and sustained withdrawal from dialysis is a rapid and recent preoperative decline in GFR, often

Figure 37.19 Blood pressure outcome for surgical revascularization in renovascular hypertension. A summary of results for more than 1200 patients. Follow-up procedures and definitions of blood pressure cure varied greatly between series. Surgical mortality was 1.3% to 5.8% in patients with stenosis from atherosclerosis and nil in those with fibromuscular disease. (Modified from reference 60.)

associated with occlusion of a critically stenotic main renal artery and a kidney with preserved size and extensive collateral supply.

Some patients develop RVH associated with total occlusion of a preexisting renal artery stenosis, resulting in nonfunction of that kidney. Hypertension in these cases may be improved by nephrectomy, which can be undertaken with a laparoscopic procedure. Results from a recent series indicate that improved blood pressures can be obtained in such instances without important loss of renal function. Estimates of renal function in this group were 11% in the removed kidney and 89% in the contralateral kidneys.⁶¹

Realistic Outcomes of Renal Revascularization

For some patients, technically successful renal revascularization leads to better BP control and improved kidney function. Antihypertensive medication requirements decrease, although rarely are they eliminated entirely. Most series report stabilization of renal function, meaning that average serum creatinine levels do not change. This interpretation may be misleading. Some patients

experience a marked improvement in renal function, whereas others have a clinically significant loss of renal function. In most series, this occurs in up to 18% to 20% of patients treated with either PTRA or surgery. Although group average values do not change, some patients experience adverse effects on renal function that should be considered for management decisions.

The benefits of modestly improved BP control and reduced antihypertensive drug requirements should not be understated. Treatment trials in primary hypertension based on BP differences of 10 to 15 mm Hg between treatment and placebo groups established major differences in cardiovascular endpoints, including overall mortality. Age and the likely ability of patients to adhere to antihypertensive drug therapy may be important considerations.

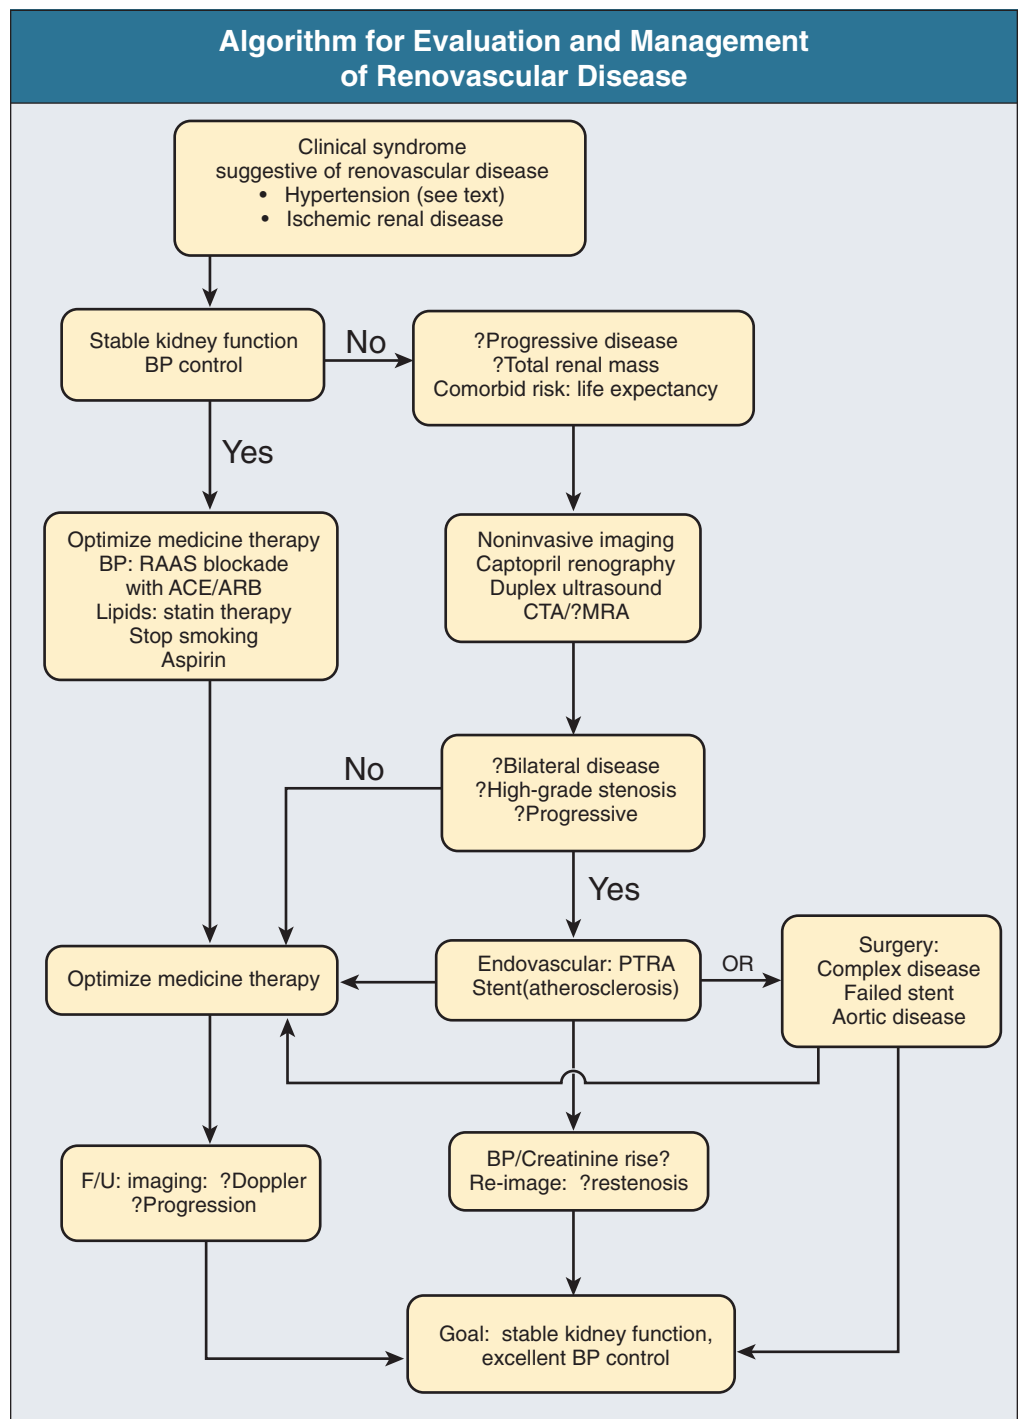

The limited prospective data comparing medical therapy with renal revascularization in the current era have demonstrated only modest benefit regarding cardiovascular outcomes for atherosclerotic disease. Each of three small, randomized trials could identify only minor differences in BP and renal outcomes.⁶²⁻⁶⁴ Recent larger trials are only now being reported; initial data from the United Kingdom regarding the ASTRAL study demonstrate no differences in renal functional, BP, CHF, or mortality endpoints during several years.³⁰ This study enrolled patients on the basis of the “uncertainty” of the clinicians (i.e., including those patients for whom benefit was not certain). No definition of certainty was provided, making it unclear exactly how these results can be generalized to wider groups. A small, randomized trial extending more than 9 years failed to detect a mortality benefit with surgical revascularization.⁶⁵ Retrospective observational reports are frequently limited by poorly standardized methods of BP measurement and drug therapy. Despite relatively few prospective trials, the application of endovascular renal artery stenting in the United States rose more than fourfold between 1996 and 2005.⁶⁶ This trend prompted the Center for Medicare and Medicaid Services to commission a formal review of the published outcome data by the Agency for Healthcare Research and Quality.⁴⁰ These authors concluded that “available evidence does not clearly support one treatment approach over another for atherosclerotic renal artery stenosis.” Among the few prospective, randomized trials, the largest was the Dutch Renal Artery Stenosis Intervention Cooperative (DRASTIC) study. It included 106 patients with relatively resistant hypertension randomized to either medical therapy or PTRA. The lack of difference in BP after 1 year between patients treated with PTRA and patients treated medically led the authors to conclude that “angioplasty has little advantage over antihypertensive drug therapy.”⁶⁴ The results of this study were analyzed under “intention-to-treat” statistical rules but were confounded by 22 of 50 patients assigned to medical therapy (44%) who crossed over to the PTRA arm because of uncontrolled BP levels at 3 months. Despite their inclusion in the medical arm, many authorities reviewing these data argue that this group offers compelling evidence of medical treatment failure in some instances and the benefit of renal revascularization for such individuals. Clinicians caring for such patients will need to consider each case individually.

An Integrated Approach to Treatment of Renovascular Disease

Aging demographics in the United States and other Western countries favor development of critical levels of renal artery stenosis in more patients than ever before. Critical to the

Figure 37.20 Algorithm for evaluation and management of renovascular disease.

The intensity of imaging and revascularization depends on both the level of kidney function and blood pressure, in addition to the comorbid disease risks for the individual subject. The overall goal should focus on stable kidney function and blood pressure levels. As with any other vascular disease, monitoring for disease progression and recurrence is an important element of long-term management. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BP, blood pressure; CTA, computed tomographic angiography; F/U, follow-up; MRA, magnetic resonance angiography; PTR, percutaneous transluminal renal angioplasty; RAAS, renin-angiotensin-aldosterone system.

management of such patients is the recognition of distinctive clinical syndromes of renovascular disease, linking acceleration of hypertension with deteriorating renal function and, occasionally, episodic circulatory congestion (flash pulmonary edema). Most patients can be managed effectively by medical means, including vigorous measures to prevent atherosclerotic progression with statin therapy, and smoking cessation. Long-term care of such patients is an ongoing process that should be reviewed at regular intervals. When progressively more complex antihypertensive regimens become required or renal function deteriorates, consideration should be given to identification and correction of critical vascular lesions affecting the kidneys.

Figure 37.20 illustrates a general algorithm by which such patients can be managed. This scheme emphasizes the need to evaluate whether the patient is a candidate for renal revascularization based on clinical features including age, other diseases, and whether stable BP and kidney function can be achieved with medical therapy. If the patient is well-controlled or is not a candidate for revascularization, there is little to be gained from extensive diagnostic studies. Conversely, if BP control and stable renal function are not achieved with medical therapy, beginning a systematic evaluation of the renal vasculature with the objective of vascular intervention is justified. The decision to undertake renal revascularization remains a highly individual judgment

based on comorbid disease risk, age, and refractoriness to therapy. In cases of atherosclerotic disease, invasive angiography now is limited mainly to patients for whom revascularization is anticipated, often at the same procedure. This approach limits the hazards of vessel instrumentation and contrast nephrotoxicity to a single procedure. Since the widespread introduction of endovascular stent procedures, surgical reconstruction is often limited to patients with technically challenging vascular lesions or associated aortic disease. Even after successful revascularization, medical therapy and follow-up remain essential. Balancing the potential risks and benefits of medical therapy versus primary revascularization remains a complex challenge.

Endocrine Causes of Hypertension—Aldosterone

I. David Weiner, Charles S. Wingo

Recent advances in the diagnosis of aldosterone-induced hypertension have led to the recognition that primary hyperaldosteronism is more common than previously thought. Effective diagnostic strategies are available, and treatment regimens are highly effective.

ETIOLOGY AND PATHOGENESIS

Aldosterone is a steroid hormone produced normally by the zona glomerulosa of the adrenal glands. Figure 38.1 shows the biochemical pathway of aldosterone production. Aldosterone synthase, which is encoded by the gene *CYP11B2*, is the rate-limiting enzyme in adrenal aldosterone production.

Figure 38.2 summarizes factors known either to stimulate or to inhibit aldosterone synthesis by the adrenal gland. Aldosterone exhibits a circadian change in plasma concentrations, greatest in the late morning and with peak values ~50% greater than the average concentration. The factors accepted as physiologically important regulators of aldosterone production include angiotensin II (Ang II), which stimulates aldosterone production through activation of the AT₁ receptor, and atrial natriuretic peptide (ANP) and chronic hypokalemia, which inhibit aldosterone production.¹

Aldosterone regulates blood pressure by several mechanisms (Fig. 38.3). These include effects on the kidneys, vasculature, central nervous system (CNS), and other endocrine hormones. No single effect is sufficient to explain the hypertension that occurs in primary hyperaldosteronism; taken together, these mechanisms explain why primary hyperaldosteronism causes refractory hypertension. Aldosterone has multiple renal effects that regulate blood pressure. First, aldosterone stimulates renal sodium chloride retention by increasing expression of the thiazide-sensitive sodium-chloride cotransporter in the distal convoluted tubule, the amiloride-sensitive epithelial sodium channel (ENaC) in the collecting duct, and the chloride-reabsorbing protein pendrin in the cortical collecting duct.³⁻⁵ Aldosterone also has acute effects on sodium reabsorption in these segments through mechanisms that do not require protein synthesis.⁶

Second, aldosterone alters blood pressure through generation of hypokalemia. The increased sodium reabsorption enhances potassium secretion. In addition, aldosterone increases extrarenal cellular potassium uptake by stimulating the ubiquitous Na⁺,K⁺-ATPase, further decreasing extracellular potassium.⁷ As discussed in Chapter 9, potassium depletion predisposes to hypertension through a variety of mechanisms.

Aldosterone has multiple effects on the vasculature. Aldosterone increases both basal vascular tone and vascular reactivity to

circulating vasoconstrictors, including norepinephrine, epinephrine, Ang II, and vasopressin.^{8,9} It decreases flow-mediated vasodilation perhaps by decreased nitric oxide (NO) production resulting from decreased endothelial nitric oxide synthase expression (NOS).¹⁰ In the CNS, aldosterone stimulates CNS-mediated sympathetic nervous tone, which further increases blood pressure.¹¹ Finally, aldosterone causes perivascular fibrosis and increases vascular expression of endothelin.¹²

Aldosterone mediates its physiologic and pathophysiologic effects predominantly by activating the mineralocorticoid receptor.¹³ The mineralocorticoid receptor is located in the inactive state in the cytoplasm; aldosterone binding to the mineralocorticoid receptor promotes a conformational change and translocation to the nucleus, where it regulates gene transcription.

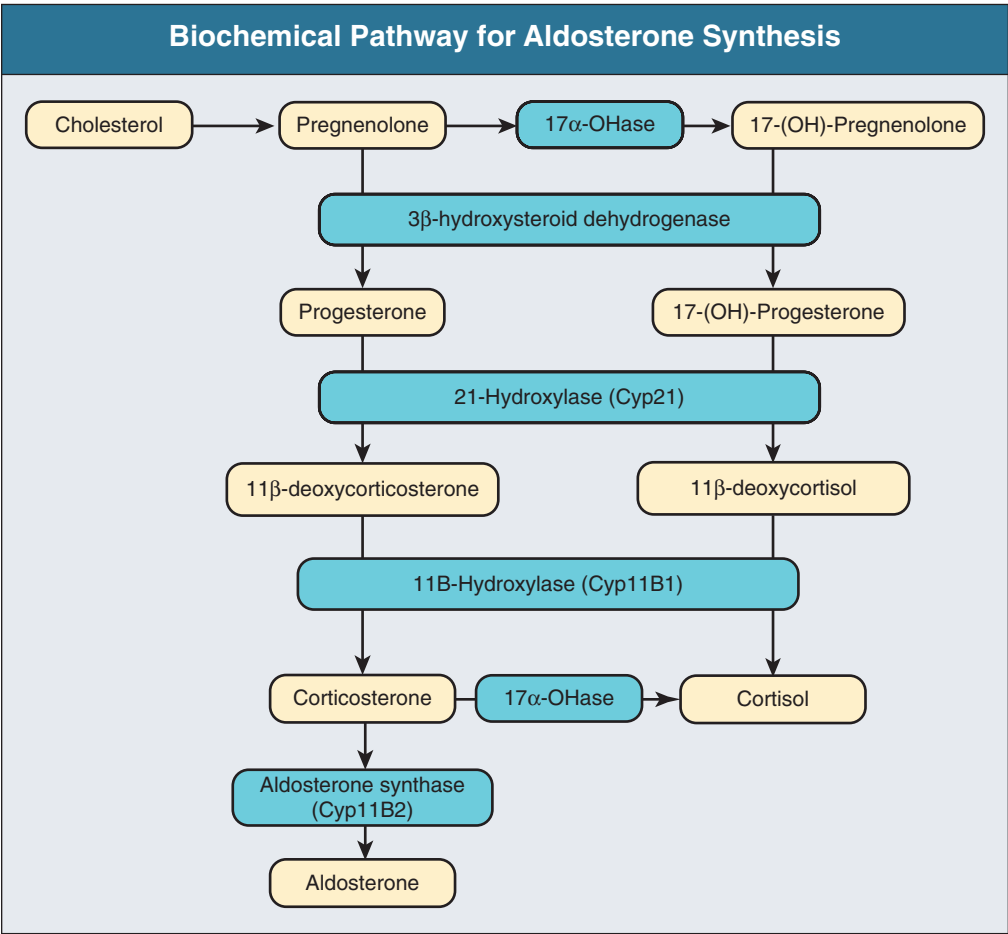

Cortisol is a naturally synthesized glucocorticoid with an affinity for the mineralocorticoid receptor similar to that of aldosterone, but it is present in plasma at ~100-fold greater levels than aldosterone. The enzyme 11 β -hydroxysteroid dehydrogenase type 2 is expressed in the aldosterone-sensitive distal nephron and collecting duct; it metabolizes cortisol to cortisone, which binds to the mineralocorticoid receptor poorly, thereby preventing glucocorticoid-dependent activation of the mineralocorticoid receptor.¹⁴ Either the genetic deficiency or the ingestion of inhibitors of 11 β -hydroxysteroid dehydrogenase can result in excessive activation of the mineralocorticoid receptor and the development of severe hypertension (see Chapter 47).¹⁴ Aldosterone also has nongenomic effects, but their role in mineralocorticoid-dependent blood pressure regulation remains unclear.^{15,16}

Primary hyperaldosteronism may result from either unilateral or bilateral adrenal disease. Typically, unilateral disease results from adenoma and bilateral disease from hyperplasia. This association is not absolute, and ~10% of those with primary hyperaldosteronism exhibit either bilateral aldosterone-producing adenoma, which may be microscopic, or unilateral hyperplasia.

EPIDEMIOLOGY

The exact incidence of primary hyperaldosteronism varies with the patient population and the diagnostic criteria used. Early studies, which recognized only severe cases, suggested that primary hyperaldosteronism was rare, with an incidence of less than 1% to 2%.¹⁷ More accurate diagnosis has led to the recognition that primary hyperaldosteronism is relatively common. Patients with treatment-resistant hypertension (i.e., inadequately controlled hypertension despite treatment with three medications at appropriate dosages including a diuretic)

Factors that Regulate Aldosterone Release

Stimulatory	Inhibitory
<i>Angiotensin II</i>	<i>Atrial natriuretic peptide</i>
<i>Adrenocorticotrophic hormone</i>	<i>Hypokalemia</i>
Acetylcholine	Calcitonin gene-related peptide
Adenosine triphosphate	Dopamine
Bradykinin	Nitric oxide
Cholecystokinin	Platelet-derived growth factor
β-Endorphin	Somatostatin
Endothelin	Unsaturated fatty acids
Enkephalins	Transforming growth factor β
Epidermal growth factor	
Hyperkalemia	
Melanocyte stimulating hormone	
Neuropeptide Y	
Neurotensin	
Norepinephrine	
Parathyroid hormone	
Prolactin	
Serotonin	
Substance P	
Vasoactive intestinal peptide	
Vasopressin	

Figure 38.2 Factors that regulate aldosterone release. Those stimuli that exert significant effects on aldosterone release under the majority of clinical circumstances are noted in italics. Stimuli listed in italic are those that are clinically most relevant; otherwise these stimuli are listed in alphabetical order. (Data from references 1 and 2.)

Figure 38.4 Incidence of primary hyperaldosteronism in patients with differing degrees of hypertension. (From reference 19.)

have a high likelihood of having primary hyperaldosteronism; rates are typically 20% to 40% and as high as 67% in some studies.¹⁸ Some studies (Fig. 38.4) have found a 1% to 2% incidence of hyperaldosteronism in normotensive patients, with the incidence increasing as blood pressure increases.¹⁹

CLINICAL MANIFESTATIONS

Patients with primary hyperaldosteronism frequently have characteristics suggestive of secondary hypertension, such as onset of hypertension between the ages of 20 and 39 years or onset in the

Typical Characteristics at Time of Diagnosis of Primary Hyperaldosteronism

Sex (female/male)	4/6
Age, yr (range)	52 \pm 1 (29–74)
Hypertension duration (yrs)	10 \pm 1.4
Number (range) of hypertensive medications	2.4 \pm 0.1 (0–4)
Percentage requiring ≥ 3 medications	53.7%
Blood pressure controlled on current medical regimen	20.4%
Neither hypokalemic nor uncontrolled on 3 or more medications	52%
Plasma aldosterone (ng/dl)	
<15	37%
15–40	54%
>40	9%
Plasma renin activity (ng Ang I/ml/hr)	0.3 \pm 0.04

Figure 38.5 Typical characteristics at time of diagnosis of primary hyperaldosteronism. (Data from reference 20.)

elderly, worsening hypertension control, and the need for multiple medications for blood pressure control. It may also present in the 40- to 50-year-old age range and may escape diagnosis for many years because of the slow worsening of hypertension. Figure 38.5 summarizes characteristics of those with primary hyperaldosteronism. Because of improved screening techniques, hypokalemia and metabolic alkalosis are no longer considered

Figure 38.6 Adrenal adenoma. An aldosterone-producing adrenal adenoma with typical cholesterol-rich yellow appearance.

hallmarks of primary hyperaldosteronism and in fact are absent in the majority of patients.

PATHOLOGY

Primary hyperaldosteronism can result either from an aldosterone-producing adenoma (Fig. 38.6) or from hyperplasia of the zona glomerulosa. Most aldosterone-producing adenomas are unilateral and are large enough (>1 cm) to be identified by computed tomography (CT) scanning (Fig. 38.7). However, aldosterone-producing adenoma may also be microscopic and may be bilateral. Hyperplasia is typically bilateral but may develop asynchronously in the two adrenal glands, and it may be unilateral. The factors that lead to either aldosterone-producing adenoma or hyperplasia are not well understood.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Evaluation of the patient with suspected primary hyperaldosteronism is directed at identifying those who have autonomous aldosterone release, then at identifying whether treatment should be based on a medical or a surgical approach. A diagnostic algorithm is shown in Figure 38.8.

Evidence of Ang II-independent aldosterone release is used to indicate autonomous aldosterone production and therefore primary hyperaldosteronism. Because Ang II cannot be assayed for routine clinical use, renin is used as a surrogate. A random blood sample is used to measure the ratio of plasma aldosterone to renin (aldosterone-renin ratio [ARR]). If this value is elevated, there is significant Ang II-independent aldosterone release, thereby providing evidence of autonomous aldosterone production consistent with primary hyperaldosteronism.

There are currently two different renin assays in routine clinical use. One measures renin activity, assayed as the rate of conversion of angiotensinogen to angiotensin I (Ang I), and the second measures the amount of immunoreactive renin. Whereas these two techniques yield results that correlate well with each other, the units and the numerical values obtained differ. For the plasma renin activity, the normal range is 1.9 to 3.7 ng Ang I/ml per hour, and the lower level of detectability is 0.2 ng Ang I/ml per hour in most clinical laboratories. For the direct renin assay, the normal range is typically 13 to 44 IU/ml, and the lower level of detectability is ~6 to 8 IU/ml. Therefore, the normal ARR, for a patient with primary hypertension not receiving medications that alter the renin-angiotensin system (RAS), is ~10:1 with the plasma renin activity and ~1:1 with the direct renin assay. The direct renin assay is less sensitive than plasma renin activity at lower values.

Whereas an elevated aldosterone level and a low renin activity are strongly suggestive of primary aldosteronism, an elevated ARR may also occur with a low aldosterone level if renin is suppressed. Combining an elevated ARR with “nonsuppressed” aldosterone levels decreases the rate of “false-positive” screening for primary hyperaldosteronism. The lowest plasma aldosterone value that may still be associated with aldosteronism is unclear; we suggest a minimum diagnostic value of 10 ng/dl.

Many common medicines may alter the ARR.^{21,22} β -Adrenergic receptor antagonists (β -blockers) suppress renin release, typically by ~50%. However, they generally will not result in complete renin suppression and generally do not confound the diagnosis of primary hyperaldosteronism.²² Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs), along with diuretics, can increase renin release in normal individuals, which theoretically might decrease the sensitivity of the ARR measurement. However, the effect of ACE inhibitors and ARBs to increase renin release can also be an advantage; in patients using either an ACE inhibitor or an ARB, suppressed renin in combination with nonsuppressed aldosterone (>10 ng/dl) is highly specific for primary hyperaldosteronism. Other anti-hypertensive medications typically have little effect on the ARR measurement.

An elevated ARR alone, although it is sensitive for detection of primary hyperaldosteronism, is not highly specific. In unselected populations or populations with only mild or moderate hypertension, as many as 50% of patients with elevated ARR do not have primary hyperaldosteronism. Current recommendations therefore suggest confirmatory testing to establish the diagnosis of primary hyperaldosteronism.^{23,24} Figure 38.9 summarizes the various confirmatory testing methods in routine use.

Once primary hyperaldosteronism is diagnosed, the clinician should determine whether unilateral aldosterone release is present, in which case adrenalectomy may be curative. If the patient is not a surgical candidate, this evaluation is not necessary. Because ~90% of patients with unilateral aldosterone release have an aldosterone-producing adenoma, an adrenal imaging protocol CT scan is the next diagnostic step; this uses

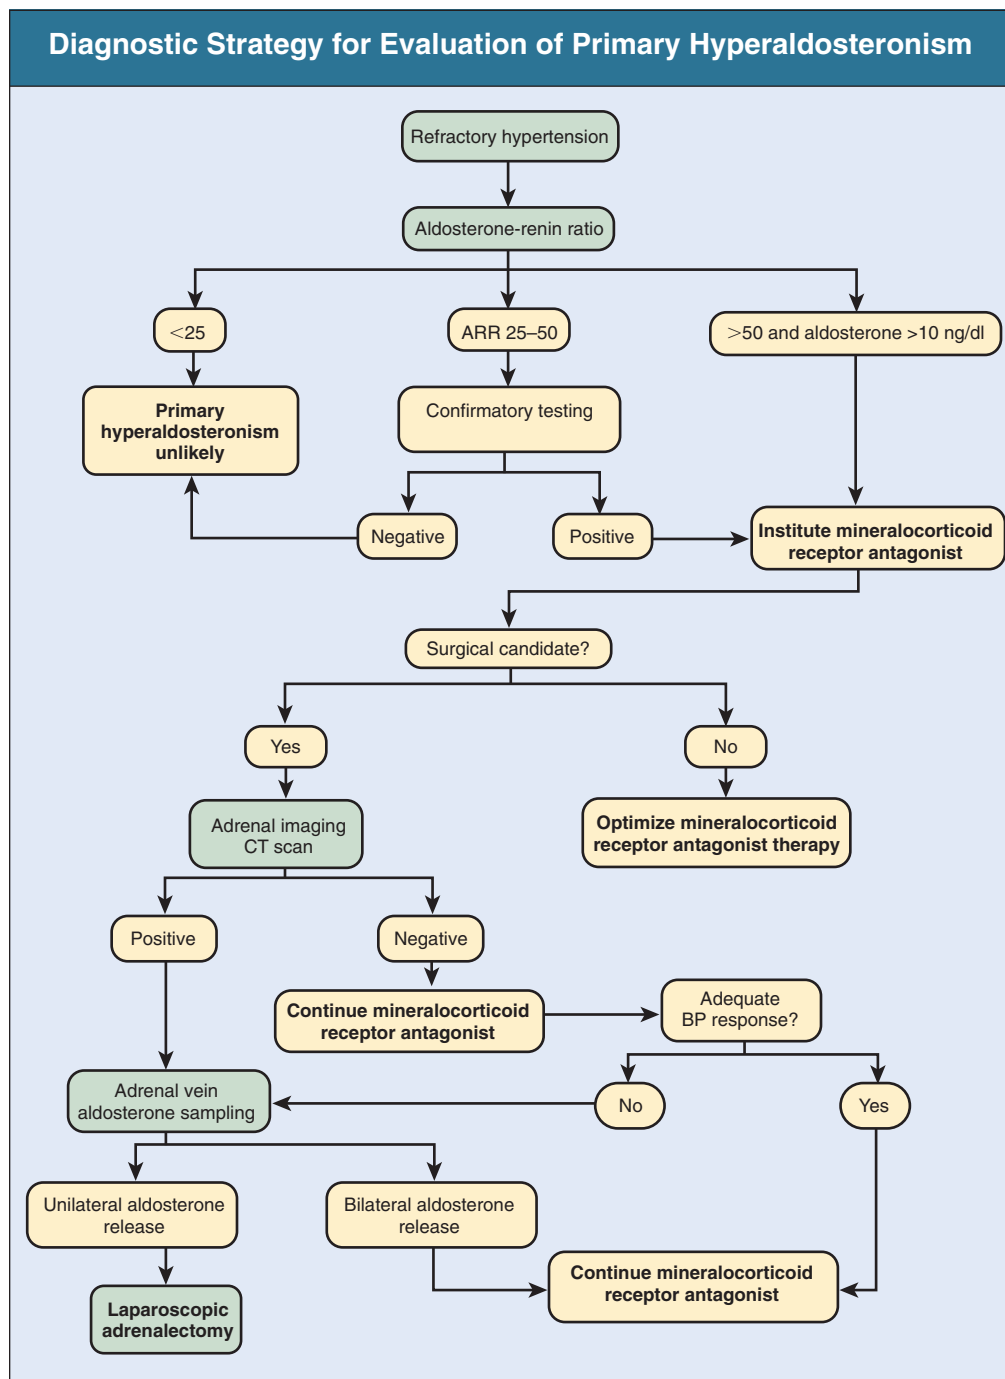

Figure 38.8 Diagnostic strategy for evaluation of primary hyperaldosteronism. ARR, aldosterone-renin ratio; BP, blood pressure; CT, computed tomography.

3-mm slices, whereas a conventional abdominal CT scan using 10-mm slices may fail to identify small adrenal adenomas.

The next step is to determine by adrenal vein sampling whether an identified adenoma is aldosterone producing or a nonfunctional adenoma (“incidentaloma”), which is present in ~5% of the adult population.

Occasionally patients will have unilateral aldosterone release but will not have an adenoma detectable on CT imaging. These patients may have either unilateral adrenal hyperplasia or micronodular aldosterone-producing adenoma. This diagnosis should be considered when the response to mineralocorticoid receptor antagonists (such as spironolactone and eplerenone) is small. Despite a normal CT scan, adrenal vein sampling is used

to identify whether the patient has surgically treatable unilateral autonomous adrenal aldosterone release.

Many other diagnostic tests have been suggested in the evaluation of primary hyperaldosteronism, but none has widespread acceptance. The postural stimulation test may help differentiate bilateral adrenal hyperplasia from an aldosterone-producing adenoma. All medicines that affect the RAS, including diuretics, β -blockers, ACE inhibitors, and ARBs, must be discontinued before testing, but the difficulty in controlling blood pressure in these patients without medicines often limits the utility of this test. Its main role is in the evaluation of patients with an adrenal adenoma and unsuccessful adrenal vein sampling.²³ Assessment of 18-hydroxysteroid metabolites may also be helpful; if elevated,

Confirmatory Testing for Diagnosis of Primary Hyperaldosteronism			
Test	Method	Evaluation	Limitations
Oral NaCl loading	Oral NaCl intake >200 mmol/d for 3 days, with oral KCl as needed to prevent hypokalemia, with subsequent 24-h urine aldosterone measurement	Urine aldosterone <10 µg/d, diagnosis unlikely; >12 µg/d, diagnosis likely	Avoid if severe uncontrolled hypertension, CKD, CHF, cardiac arrhythmias, or severe hypokalemia
Saline infusion test	Patient in recumbent position for 1 h before testing and then throughout entire test. Begin test between 8:00 and 9:30 am. Measure plasma aldosterone, plasma renin activity, cortisol, and potassium at beginning of test and then after infusion of 2 L/NS IV during 4 h	Plasma aldosterone at end of infusion <5 ng/dl, diagnosis unlikely; <10 ng/dl diagnosis likely; 5–10 ng/dl, indeterminate	Avoid if severe uncontrolled hypertension, CKD, CHF, cardiac arrhythmias, or severe hypokalemia
Fludrocortisone suppression test	Fludrocortisone, 0.1 mg PO every 6 h for 4 days, plus oral NaCl, 30 mmol 3x/d, and high-salt diet combined with sufficient KCl to avoid hypokalemia	Upright plasma aldosterone on day 4 >6 ng/dl and plasma renin activity <1 ng/ml/hr, diagnosis likely	Frequently requires hospitalization for patient monitoring of blood pressure and potassium
Captopril challenge test	Oral captopril, 20–50 mg, with plasma aldosterone and plasma renin activity obtained immediately before captopril and then 1–2 h afterward, with patient seated throughout test	Plasma aldosterone decrease >30%, diagnosis unlikely	Probably more false-positive and false-negative results than other tests

Figure 38.9 Confirmatory testing for primary hyperaldosteronism. CHF, congestive heart failure; CKD, chronic kidney disease; NS, normal saline. (From reference 23.)

they suggest an aldosterone-producing adenoma,²⁵ but the diagnostic accuracy is inadequate to plan therapy with certainty.

Rare patients with an elevated ARR have familial hypertension type 1, also known as glucocorticoid-remediable aldosteronism. In this condition, there is crossover between the *CYP11B1* and *CYP11B2* genes, producing a chimeric gene, which results in regulation of aldosterone synthase expression by adrenocorticotrophic hormone (ACTH) and excessive aldosterone release.^{26,27} Glucocorticoid-remediable aldosteronism should be considered in children or young adults with refractory hypertension or in whom there is a family history of hypertension in the same age range or history of premature hemorrhagic stroke.²³ If it is suspected, genetic testing is now the preferred diagnostic approach because of improved sensitivity and specificity over measurement of corticosteroid metabolites or dexamethasone suppression testing.^{23,24} If glucocorticoid-remediable aldosteronism is identified, administration of glucocorticoids in the minimal dose necessary to suppress ACTH release can dramatically improve blood pressure control (see Chapter 47).

NATURAL HISTORY

The natural history of untreated primary hyperaldosteronism is uncertain. Although there are case reports of remission of primary hyperaldosteronism, these all followed adrenal venography and may reflect complications related to the venography. Therefore, treatment is universally recommended.

TREATMENT

Patients with an aldosterone-producing adenoma who are acceptable surgical candidates should undergo surgical laparoscopic adrenalectomy. Laparoscopic adrenalectomy is associated with a shortened hospital stay, a decreased postoperative morbidity, and a quicker return to normal health compared with open surgical adrenalectomy. Patients who undergo laparoscopic adrenalectomy have a 30% to 60% chance of hypertension cure.^{28–30} Patients most likely to be cured of their hypertension are younger than 50 years and have few family members with primary hypertension. Those not cured have a more than 95% chance of improvement in their blood pressure.^{29,30} The lack of complete cure may reflect intrarenal microvascular disease that developed as a consequence of the poorly controlled hypertension.

Those who are not candidates for surgical adrenalectomy or who have bilateral aldosterone production should be treated with mineralocorticoid receptor antagonists. Figure 38.10 summarizes characteristics of the two major mineralocorticoid receptor antagonists currently available, spironolactone and eplerenone. Both are highly effective, and their major difference relates to their side effect profiles and their costs. Spironolactone has partial affinity for both androgenic and progesterone receptors, resulting in dose-related side effects. For example, gynecomastia occurs in ~7% of men treated with 50 mg daily or less but in more than 50% of those treated with 150 mg or more daily.³¹

Comparison of Currently Available Aldosterone-Receptor Antagonists		
Medication	Dose Range (mg/day)	Common Side Effects
Spironolactone	25–400	Gynecomastia Breast pain (mastodynia) Impotence Decreased libido Menstrual irregularities
Eplerenone	25–200	Generally well tolerated Gynecomastia or abnormal vaginal bleeding in <2%

Figure 38.10 Comparisons of the different mineralocorticoid receptor antagonists.

Eplerenone has affinity for the mineralocorticoid receptor similar to that of spironolactone but ~100-fold less affinity for androgenic and progesterone receptors than spironolactone.³² Accordingly, the incidence of side effects related to androgenic or progesterone receptor activation, such as gynecomastia, gynecodynia (breast pain), vaginal bleeding, and impotence, is greatly reduced. Eplerenone use may be limited because of greater cost.

Treatment with a mineralocorticoid receptor antagonist usually results in dramatically improved blood pressure control. Many patients will respond to a low dose, 25 to 50 mg daily, as initial therapy. Both systolic and diastolic blood pressure frequently decrease by ~25 mm Hg during a period of a few weeks to months. Dosage of the mineralocorticoid receptor antagonists can be increased as necessary but generally should not be changed more frequently than every 2 to 4 weeks. Hypokalemia and metabolic alkalosis, if present, improve. Potassium supplements can be tapered rapidly with improvement of hypokalemia. With time, blood pressure can be controlled in many patients with a mineralocorticoid receptor antagonist and a single alternative agent. We typically use ACE inhibitors because renin activity, which is suppressed initially, typically increases after mineralocorticoid receptor antagonist therapy is started. Synergistic use of an ACE inhibitor may prevent development of a renin-stimulated, Ang II-dependent component of hypertension. However, many antihypertensive combinations can be used successfully with the mineralocorticoid receptor antagonist.

Aldosterone Breakthrough

RAS inhibition is widely used to slow the progression of chronic kidney disease (CKD) and to decrease cardiovascular mortality in patients with congestive heart failure. These treatment regimens usually involve either ACE inhibitors or ARBs, which, by blocking Ang II-dependent stimulation of aldosterone production, should decrease plasma aldosterone levels. However, many patients develop “aldosterone breakthrough,” in which the initial decrease in plasma aldosterone is followed by a later rise in aldosterone levels to greater than before ACE inhibitor or ARB treatment. Aldosterone breakthrough is associated with faster loss of glomerular filtration rate (GFR) in patients with CKD, reduced exercise capacity and reduced venous compliance in patients with congestive heart failure, and adverse effects on left ventricular mass index in hypertensive patients.^{33,34} Patients with

CKD who develop aldosterone breakthrough have a greater rate of loss of GFR, and treatment of these patients with low doses of mineralocorticoid receptor antagonists, such as spironolactone, 25 mg orally once a day, appears to decrease proteinuria, predicting a renoprotective benefit.³⁵

Endocrine Causes of Hypertension

A. Mark Richards, M. Gary Nicholls

The true incidence and prevalence of hypertension with endocrine etiology are unknown. However, primary aldosteronism, the most common form, is reported in 2% to 12% of patients with newly diagnosed hypertension. Overall, an endocrine contribution to high blood pressure may be present in more than 10% of cases. Endocrine hypertension often remains undiagnosed because physicians consider it rare and therefore unlikely, and access to the required specialized tests is limited.

Endocrine hypertension may occur in the absence of readily observed signs, symptoms, or abnormalities in routine biochemical tests. However, certain features should trigger a simple screen (Fig. 39.1), such as a family history of inherited conditions, including pheochromocytoma, neurofibromatosis, multiple endocrine neoplasia, and aldosteronism. Refractory hypertension (i.e., blood pressure resistant to administration of three antihypertensive drugs of different classes) mandates consideration of secondary hypertension, provided iatrogenic factors and noncompliance have been ruled out. The differential diagnoses will include endocrine, renal, and renovascular disease.

Symptoms and signs may be present. Severe hypokalemia may cause weakness, polyuria, and cardiac arrhythmia. Hyperadrenergic symptoms occur with pheochromocytoma. Changes in temperature tolerance, body weight, hair and skin condition, and bowel habit are clues in thyroid dysfunction or hypercortisolism. Thyroid disease, Cushing's syndrome, and acromegaly are associated with typical changes in body habitus. Abnormal sweating occurs in pheochromocytoma, thyrotoxicosis, and acromegaly.

Hypokalemia and diabetes mellitus are hallmarks of endocrine pathologic processes in hypertension. Hypokalemia in the absence of diuretic use should suggest diagnoses such as primary aldosteronism, pseudoaldosteronism, renin-secreting tumor, Cushing's disease, and accelerated hypertension of any cause. Therefore, concurrent high blood pressure and hypokalemia should prompt consideration of endocrine hypertension. Hyperglycemia is common to Cushing's syndrome, pheochromocytoma (especially when epinephrine levels are increased), acromegaly, and primary aldosteronism.

Diagnosis of endocrine forms of hypertension often offers the chance of cure, of altering an otherwise catastrophic natural history (e.g., in pheochromocytoma), and of applying specific and effective therapies that ameliorate other elements of the disease beyond control of blood pressure. Aldosteronism is addressed in Chapter 38. The following sections address other types of endocrine hypertension.

CUSHING'S SYNDROME

Definition

This syndrome of sustained glucocorticoid excess is most commonly secondary to production of adrenocorticotrophic hormone (ACTH) by a pituitary adenoma (Cushing's disease). Less frequently, it is the result of cortisol overproduction from an adrenal adenoma or carcinoma, and rarely it may be secondary to ectopic ACTH or corticotropin secretion.¹ It can also result from exogenous corticosteroid administration. The incidence of endogenous Cushing's syndrome is 5 to 10 cases per million population per year. Cushing's disease and cortisol-secreting adrenal tumors are four times more common in women than in men. Approximately 0.5% of patients with bronchogenic carcinoma (more common in men than in women) develop ectopic ACTH syndrome.

Etiology, Pathogenesis, and Epidemiology

Hypertension is present in 80% of patients with Cushing's syndrome (less often when it is due to exogenous synthetic glucocorticoid administration) and results from an increase in both cardiac output and total peripheral resistance. The mechanisms underlying these hemodynamic changes are complex.² In some subjects, it may be due to concurrent overproduction of mineralocorticoids (aldosterone, 11-deoxycorticosterone, or corticosterone). Cortisol, although it is capable of binding the mineralocorticoid receptor, usually does not. This is because of the renal enzyme 11 β -hydroxysteroid dehydrogenase type 2 (β -HSD2), which inactivates cortisol to corticosterone, thereby preventing its binding to the mineralocorticoid receptor. However, in the setting in which β -HSD2 activity is low or in which cortisol levels are extremely high (such as in ectopic ACTH syndrome), there may be sufficient excess cortisol that binding to the mineralocorticoid receptor occurs. Inhibition of the vasodilator nitric oxide (NO) by cortisol may also contribute to the hypertension, along with enhanced pressor responsiveness to catecholamines and angiotensin II (Ang II), heightened cardiac inotropic sensitivity to β -adrenergic stimulation, and increased plasma volume.² The sympathetic nervous and the renin-angiotensin systems are, if anything, suppressed even though circulating levels of renin substrate are increased. The possibility that elevated levels of vasoconstrictor hormones (vasopressin,

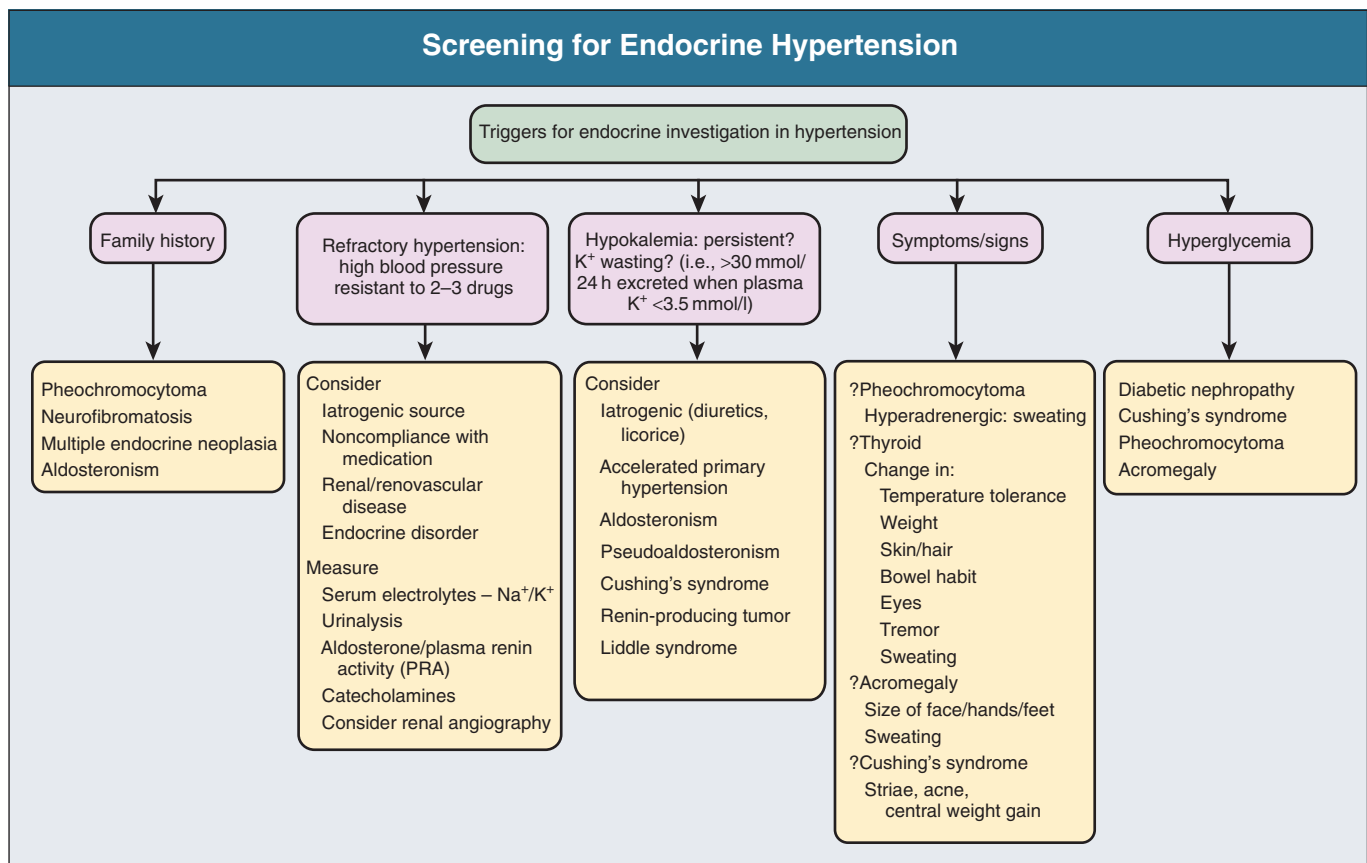

Figure 39.1 Screening for endocrine hypertension. Clinical observations suggesting endocrine investigation in hypertension.

endothelin 1, thromboxane, erythropoietin [EPO], and insulin) or subnormal concentrations of vasodilator systems (kallikrein-kinins and prostaglandins) contribute to the hypertension of Cushing's syndrome has been raised, but the evidence is frail.² The vasodilator atrial natriuretic peptide (ANP) is elevated in Cushing's syndrome, although biologic responses to ANP are impaired; in theory, ANP resistance could also contribute to the hypertension.³ Successful treatment of Cushing's disease or removal of an underlying adrenal adenoma usually results in a reduction of blood pressure and partial return of the previously impaired nocturnal fall in arterial pressure, although hypertension persists in a sizable minority of patients.

Clinical Manifestations

Clinical features in Cushing's disease result from elevated circulating levels of pro-opiomelanocortin hormones including ACTH (increased pigmentation) and cortisol (central adiposity, muscle wasting and weakness, plethoric facies, purple striae [Fig. 39.2], easy bruising, osteoporosis, psychological problems). In some patients, androgen effects are observed (hirsutism, acne, virilization), and these may be striking in those with adrenal adenoma or carcinoma. Ectopic ACTH syndrome due to small cell bronchogenic carcinoma or other tumors (e.g., bronchial or thymic carcinoid) presents typically as a wasting disease often with hyperpigmentation and hypokalemia. Hypertension is often associated with left ventricular hypertrophy, which can be disproportionate to the blood pressure, and frank cardiac failure is occasionally the presenting feature.⁴

Figure 39.2 Striae and central obesity of Cushing's syndrome.

Differential Diagnosis

Pseudo-Cushing's syndrome can occur with a sustained high intake of alcohol (by inducing augmented cortisol secretion and reduced cortisol metabolism due to hepatic damage); in depression; and in obesity, in which the plasma clearance rate of cortisol is increased, leading to a slightly elevated production rate of cortisol, but plasma levels of the hormone are normal. A careful physical examination differentiates obesity from Cushing's syndrome in all but a few patients.

Diagnosis

An elevated urinary free cortisol excretion (or early morning cortisol to creatinine ratio) and absence of suppression of 8 AM plasma cortisol after a low dose of dexamethasone (1 mg at mid-night) are the commonly used initial tests.

Further key investigations include computed tomography (CT) and magnetic resonance imaging (MRI) of the pituitary and adrenals (and also the thorax, abdomen, and pelvis when ACTH-producing carcinoid tumors are suspected), plasma ACTH (which is suppressed in cortisol-secreting adrenal tumors but elevated in the ectopic ACTH syndrome), high-dose dexamethasone test (which partially suppresses ACTH in cases of pituitary tumors but not with ectopic ACTH), corticotropin-releasing hormone test, and simultaneous bilateral inferior petrosal sinus sampling for ACTH measurements. The last test is useful in differentiating Cushing's disease from ectopic ACTH syndrome when the previously listed tests give equivocal results.

Treatment and Prognosis

Untreated, Cushing's syndrome has a 50% 5-year mortality due to cardiovascular risk from hypertension along with glucose intolerance and insulin resistance, hyperlipidemia, obesity, and elevated fibrinogen levels.⁵

Cure rates in treatment of Cushing's disease are 80% to 90% by selective removal of a pituitary microadenoma and 50% for pituitary macroadenomas. Cushing's syndrome due to an adrenal adenoma is almost always cured by unilateral adrenalectomy. However, when the underlying lesion is adrenal carcinoma, most patients succumb within 2 years. The prognosis is also poor when Cushing's syndrome results from ectopic ACTH syndrome due to small cell bronchogenic carcinoma. If the ACTH-producing tumor is benign and can be located, however, removal usually leads to cure. After cure of Cushing's syndrome, approximately 30% of patients have persistent hypertension.⁶

In managing the hypertension due to Cushing's syndrome, there is no good evidence to support the use of any class of antihypertensive drug over another. Potassium-losing diuretics can exacerbate both hypokalemia and glucose intolerance, whereas potassium-sparing diuretics, usually in combination with other antihypertensive agents, may correct hypokalemia and reduce edema while lowering the blood pressure.

PHEOCHROMOCYTOMA

Definition

This disorder has challenged and fascinated clinicians since its first description by Frankel in 1886. Clinical manifestations can mimic a wide spectrum of other disorders; hence, the diagnosis is frequently delayed or missed altogether, sometimes with fatal consequences.⁷

Pheochromocytoma refers to a dusky tumor whose cells stain brown with chromium salts. Such tumors arise most commonly within the adrenal glands (Fig. 39.3), but approximately 10% are extra-adrenal (paraganglioma). Although the majority are benign, around 10% metastasize to regional lymph nodes and beyond. Histologic features are not a reliable guide to malignant behavior. The tumors can secrete a wide variety of hormones but most characteristically produce norepinephrine, epinephrine, and dopamine, with patterns differing between patients. Few paragangliomas produce epinephrine. Very high dopamine

Figure 39.3 Large adrenal pheochromocytoma with areas of hemorrhagic necrosis.

production is associated with malignant disease or a large tumor mass.

Etiology, Pathogenesis, and Epidemiology

The prevalence of pheochromocytoma in patients with hypertension in general medical outpatient clinics is 0.1% to 0.6%.⁸ Because as many people die with unsuspected pheochromocytoma as with a firm diagnosis, however, the prevalence may be considerably higher.⁹

Pheochromocytomas can be sporadic or familial. Whereas sporadic cases are usually unicentric and unilateral, familial pheochromocytomas are often multicentric and bilateral. Familial pheochromocytomas are the result of a germline mutation in one of five genes: the *RET* gene leading to multiple endocrine neoplasia type 2; the von Hippel-Lindau (*VHL*) gene, which causes the von Hippel-Lindau syndrome; the neurofibromatosis type 1 (*NFI*) gene resulting in von Recklinghausen's disease; and the genes encoding the B and D subunits of mitochondrial succinate dehydrogenase (*SDHB* and *SDHD*), which are associated with familial paragangliomas and pheochromocytomas. Clinical features of syndromes associated with pheochromocytoma are described in Figure 39.4. For patients with apparently sporadic pheochromocytomas, an underlying germline mutation of the genes mentioned may be present in around 20% of cases and should be considered in younger patients (<50 years) and those with multifocal or extra-adrenal tumors.^{8,10} Patients found to harbor a germline mutation need to be identified for appropriate guidance of medical management for them and their families.

Clinical Manifestations

Clinical features reflect episodic or continuous overproduction of catecholamines and depend in part on which catecholamine dominates. Symptoms include headache, sweating, palpitations, anxiety, and pallor (Fig. 39.5).¹¹ Hypertension or diabetes mellitus, with or without symptoms, may be the initial manifestation. Alternatively, pheochromocytoma may present as a tumor mass, usually an enlarging primary lesion in the abdomen or a paraganglioma in the neck, ear, thorax, or abdomen. On occasion, a metastatic lesion may be the presenting sign. Physical examination may reveal labile (66%) or persistent (33%) hypertension,

Main Clinical Features of Syndromes Associated with Pheochromocytoma	
von Hippel-Lindau syndrome	Renal cell cysts and carcinomas
Type 1 (no pheochromocytoma)	Retinal and CNS hemangioblastomas
	Pancreatic neoplasms and cysts
	Endolymphatic sac tumors
	Epididymal cystadenomas
Type 2 (with pheochromocytoma)	A. Retinal and CNS hemangioblastomas
	Pheochromocytomas
	Endolymphatic sac tumors
	Epididymal cystadenomas
	B. Renal cell cysts and carcinomas
	Retinal and CNS hemangioblastomas
	Pancreatic neoplasms and cysts
	Pheochromocytomas
	Endolymphatic sac tumors
	Epididymal cystadenomas
	C. Pheochromocytomas only
Multiple endocrine neoplasia (MEN) type 2*	A. Medullary thyroid carcinoma
	Pheochromocytoma
	Hyperparathyroidism
	Cutaneous lichen amyloidosis
	B. Medullary thyroid carcinoma
	Pheochromocytoma
	Multiple neuromas
	Marfanoid habitus
Neurofibromatosis type 1	Multiple fibromas on skin and mucosae
	Café-au-lait skin spots
	Pheochromocytomas
Paraganglioma syndromes	Head and neck tumors (carotid body tumors; vagal, jugular, and tympanic paragangliomas)
	Pheochromocytomas
	Abdominal or thoracic paragangliomas (or both)

Figure 39.4 Main clinical features of syndromes associated with pheochromocytoma. CNS, central nervous system. *A third type of MEN type 2 consists of familial medullary thyroid carcinoma only (without pheochromocytoma).

Figure 39.5 Frequency of symptoms in 324 patients with pheochromocytoma. (Modified from reference 11.)

sometimes with reciprocal changes in blood pressure and heart rate when the tumor secretes norepinephrine predominantly.¹² The patient may have cool, mottled extremities and a low-grade fever with tachycardia and postural hypotension. Patients may also present as an emergency with severe hypertension with or without heart failure and a variety of symptoms attributable to high plasma catecholamines. This can occur after minor or major trauma, at the time of delivery, or apparently spontaneously owing to sudden release of catecholamines from or hemorrhage into the tumor. Pheochromocytoma in pregnancy presents particular difficulties in diagnosis and management.¹³

Diagnosis

Diagnosis of pheochromocytoma is based on clinical suspicion but demands biochemical confirmation (Fig. 39.6). Current evidence is that plasma free metanephrines provide the best

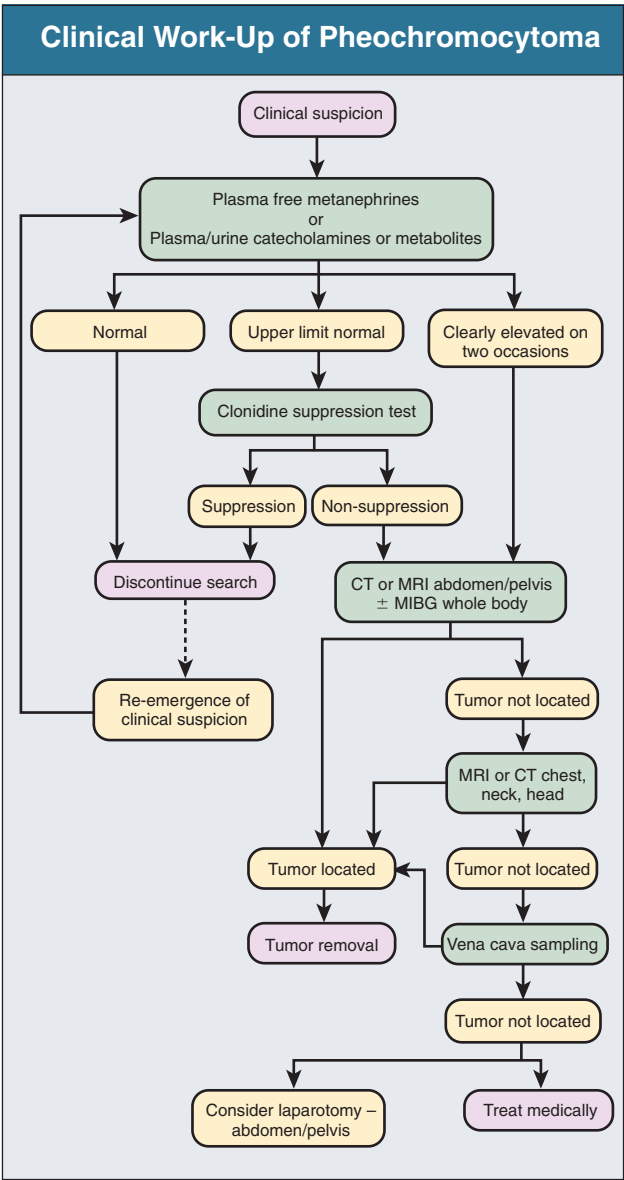

Figure 39.6 Clinical work-up of pheochromocytoma. CT, computed tomography; MIBG, metaiodobenzylguanidine; MRI, magnetic resonance imaging.

biochemical test for diagnosis or exclusion of pheochromocytoma, and the levels are relatively independent of renal function while also providing some guidance for tumor size and location.¹⁴⁻¹⁶ When plasma free metanephrines are not available, plasma or urinary catecholamines or their other metabolites may be used and typically are 5- to 10-fold greater than normal. When catecholamine levels are at the upper limits of normal, a suppression test with clonidine (which suppresses plasma norepinephrine into the normal range if there is no pheochromocytoma but fails to do so in patients harboring a pheochromocytoma) is useful.¹⁷

Once a firm biochemical diagnosis is secured, the lesion must be localized (see Fig. 39.6). Imaging of a pheochromocytoma requires realization that the tumor, like the clinical syndrome itself, may mimic other lesions.¹⁸ MRI or CT scan of the abdomen and pelvis, concentrating first on the adrenals, is successful in most patients, but additional investigations may be required if no lesion is detected. Such investigations may include selective venous sampling to detect a step-up in catecholamine levels, metaiodobenzylguanidine (MIBG) scanning, indium In 111-labeled octreotide scanning, measurements of plasma free metanephrines coupled with vena caval sampling, and positron emission tomography (PET) scanning.¹⁹ Removal of a pheochromocytoma-containing adrenal can result in compensatory medullary hyperplasia in the contralateral adrenal, giving a false-positive MIBG scan; hence, interpretation must be cautious.²⁰

Treatment

Once the tumor has been localized, the patient should be prepared for surgery with a collaborative team approach by the surgeon, anesthesiologist, and physician. Blockade of α -adrenoceptors, usually with phenoxybenzamine, with the later addition of β -blockade if it is necessary to control blood pressure and tachycardia, should be implemented for some weeks before surgery. β -Blockade monotherapy is contraindicated because of the risk of unopposed α -adrenergic stimulation leading to catastrophic hypertensive crisis. Alternative drugs that have been used successfully before surgery include prazosin (α -blocker) and labetalol (combined α - and β -blocker).

A laparoscopic approach to surgical removal of adrenal pheochromocytomas and some extra-adrenal tumors has gained widespread acceptance, but the laparoscopic approach should be converted to open adrenalectomy for difficult dissection, invasion, adhesions, or surgical inexperience.²¹ Laparoscopic surgery has also been used successfully for hereditary bilateral or recurrent pheochromocytoma. Agents used to achieve intraoperative blood pressure control include phentolamine, sodium nitropruside, and magnesium sulfate.

Hypotension and hypoglycemia are potential postoperative problems. In most cases, surgical removal of pheochromocytoma normalizes plasma catecholamine levels and previously suppressed central sympathetic outflow. Whereas blood pressure often improves with removal of the pheochromocytoma, it remains elevated in some patients, especially in those whose hypertension had been persistent as opposed to episodic. These subjects require long-term antihypertensive therapy.

For malignant pheochromocytoma, consideration should be given to aggressive surgical resection, particularly when there is a single metastatic lesion. Symptoms should be controlled with α - and β -blocking agents as needed, and irradiation can be useful for bone metastases. Chemotherapy, usually with

cyclophosphamide, vincristine, and dacarbazine, should be considered for those with surgically inaccessible metastases producing symptoms that cannot be controlled by α - and β -blockade. Progression of malignant pheochromocytoma is extremely variable, with survival for decades in some cases. Median survival is approximately 5 years.

ADRENAL INCIDENTALOMA

Definition and Epidemiology

“Incidentaloma” refers to the incidental discovery of an adrenal mass in the course of investigation for other conditions in the absence of any prior suspicion of adrenal disease.²² The increasing use and sophistication of abdominal imaging for a wide range of indications frequently leads to the incidental discovery of an adrenal mass. Current prevalence of unsuspected adrenal masses is reported at between 1% and 5% (less than 1% in those younger than 30 years, rising to 7% in those older than 70 years). Hypertension is more common in those with incidentalomas (40%) than in the general population. In a substantial series of more than 1000 incidentalomas, about 75% proved to be nonsecretory benign adenomas. However, an important minority (approximately 20%) showed endocrine activity, including aldosteronoma (1.4%, frequently normokalemic), pheochromocytoma (4.2%, with half normotensive), and cortisol-secreting tumors (9.2%, frequently with subclinical cortisol excess).²²

Importantly, adrenal carcinoma, although rare at 0.6 to 2.0 cases per million population, accounted for 4% of cases in a large and well-documented series of incidentalomas. Adrenal carcinoma is more likely with increasing size of the adrenal mass (2% of masses up to 4 cm in diameter, 6% of masses 4 to 6 cm in diameter, and 25% of tumors larger than 6 cm). Adrenal carcinomas may or may not be functional. The prognosis is poor, with a 5-year survival of less than 20%. The differential diagnosis of incidentalomas includes metastases, myelolipoma, ganglioneuromas, cysts, hemorrhage, and infections.

Management

Incidentalomas mandate a careful history, directed at possible symptoms of endocrine hypertension; physical examination; and initial screening for pheochromocytoma (urine free metanephrines), glucocorticoid excess (urinary free cortisol to creatinine ratio and early morning plasma cortisol concentration after 1 mg dexamethasone), or primary aldosteronism (plasma and 24-hour urinary potassium levels and plasma renin to aldosterone ratio) as outlined in the relevant sections of this chapter and the chapter on primary aldosteronism.

RENIN-SECRETING TUMOR

Definition

Primary renin-secreting tumors are rare. Diagnostic criteria include an elevated plasma renin or prorenin level, which decreases on removal of the tumor, and demonstration of renin within the tumor. Most cases are due to benign renal juxtaglomerular cell tumors ranging from 5 mm to 6 cm in diameter, but they occasionally occur with nephroblastomas, renal cell carcinomas, and extrarenal neoplasms (bronchial or pancreatic carcinoma, ovarian tumors, carcinoma of ileum or colon, soft tissue sarcomas, orbital hemangiopericytoma).

Etiology and Pathogenesis

Autonomous hypersecretion of renin results in high circulating levels of Ang II, which increase arterial pressure. Secondary hyperaldosteronism, giving rise to hypokalemia, results from stimulation of the adrenal glomerulosa by Ang II. High Ang II levels also induce hyponatremia in a minority of patients (by stimulation of thirst and antidiuretic hormone secretion together with a direct renal water-retaining action of the peptide) and may also cause proteinuria.²³

Clinical Manifestations

Cases show slight female predominance; 75% of patients are younger than 30 years, presenting usually with severe, occasionally paroxysmal hypertension (average 206/131 mm Hg), hypokalemia (<3.0 mmol/l in approximately 70% of cases), proteinuria (>0.4 g/day in around 50% of patients), and, in a minority, hyponatremia.²⁴ Glomerular filtration rate (GFR) is normal or high. Blood pressure may decrease substantially with the first dose of angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB).

Pathology

Renin-secreting tumors are encapsulated and tan or grayish yellow, with scattered hemorrhages. They consist largely of polygonal or spindle cells in close contact with capillary and sinusoidal vessels and contain cytoplasmic renin granules.²⁴

Diagnosis and Differential Diagnosis

Patients presenting with hypertension and hypokalemia together with elevated renin (and prorenin) and aldosterone levels may harbor a renin-secreting tumor, among which a renal juxtaglomerular cell tumor is most common. Renal artery stenosis or occlusion must first be ruled out by CT or MRI angiography or renal arteriography. These investigations also might reveal a radiolucent, relatively avascular, usually peripheral juxtaglomerular cell tumor (Fig. 39.7).²⁵ CT and MRI scans showing an isodense or hypodense lesion with little or no enhancement after injection of contrast material have proved helpful in the provisional localization of these tumors. Bilateral, simultaneous renal vein sampling may enable lateralization of the tumor. Because renal blood flow to the culprit kidney is not impaired, however, a renin ratio of more than 1.2:1 between the two renal veins may not be present, in contrast to the situation of unilateral renal artery stenosis, in which reduced blood flow to the stenosed kidney and renin oversecretion contribute to an often high renal vein renin ratio. Selective segmental renal vein renin sampling may help localize the tumor. When no renal lesion can be visualized and lateralization of renin secretion is not evident, an extra-renal renin-secreting lesion must be considered and sought by appropriate radiographic investigations and venous sampling for renin measurements.

Apart from renal artery stenosis or occlusion, it may be necessary to exclude other renin-producing lesions including Wilms' tumor, renal carcinoma, neuroblastoma, hepatocellular carcinoma, and pheochromocytoma, which can either themselves secrete renin or, alternatively, stimulate renal renin production. A careful clinical history and physical examination together with selected radiography and, occasionally, selective venous sampling for measurements of renin should, in most

Figure 39.7 Renin-secreting tumor. Left renal angiography arterial (A) and nephrogram (B) phases revealing a 2.5-cm juxtaglomerular cell tumor with a circumscribed and relatively avascular appearance at the upper pole (arrows). (Modified from reference 25.)

instances, differentiate these disorders from a juxtaglomerular cell tumor.

Treatment

Preoperative control of arterial pressure is based on an ACE inhibitor or ARB, introduced with caution to avoid first-dose

hypotension. For juxtaglomerular cell tumors, local excision, where possible, is advisable to preserve nephrons. When doubt exists, an intraoperative frozen section will differentiate a benign juxtaglomerular cell tumor from malignant lesions and guide surgery. Removal of a juxtaglomerular cell tumor results in the return of renin and aldosterone levels to normal. Blood pressure decreases rapidly, but not always to normal if there is a background of primary hypertension or when there is hypertensive vascular damage.

ACROMEGALY

Definition and Epidemiology

Acromegaly is caused by excessive circulating growth hormone (GH), usually from a pituitary tumor. It is rare, with a prevalence of 40 cases per million. Hypertension is more common in acromegaly than in the general population, with an estimated 35% of subjects with a diastolic blood pressure above 100 mm Hg and higher frequencies in female and older patients. Uncertainty about the prevalence (between 17.5% and 57% in more than 20 different reports) reflects variation in definitions of hypertension and the stage of the disease.²⁶ Acromegalic patients who have additional hypopituitarism or advanced cardiac disease may have blood pressure reduction masking prior hypertension.

The pathogenesis of hypertension in acromegaly is complex but reflects sodium retention and volume expansion associated with an inappropriate response of hormonal systems to counteract these effects. Total exchangeable sodium, total body water, and extracellular fluid volume are increased. Volume expansion should suppress plasma renin levels, but although levels are low, they are not consistent with the sodium status. Aldosterone levels are also normal or only slightly suppressed. Plasma ANP, which should be elevated in the volume-expanded state, remains normal in acromegaly. The kidneys are enlarged and GFR is increased, but sodium balance is not corrected unless the acromegaly is cured. Other mechanisms contributing to hypertension may include the presence of circulating endogenous Na^+, K^+ -ATPase (digoxin-like substances), GH-induced vascular hypertrophy resulting in decreased vascular compliance, effects on the sympathetic nervous system (SNS), and undefined genetic factors.

Clinical Manifestations

Acromegaly is characterized by enlargement of the skull (Fig. 39.8), hands (Fig. 39.9), and feet. Other symptoms result from local effects of an expanding pituitary tumor and include visual field defects and headache. Signs and symptoms include headache (40%), excessive sweating (50%), loss of libido (35%), amenorrhea (45%), carpal tunnel syndrome (25%), diabetes mellitus (19%), and visual field defects (5%).^{27,28} Thyroid enlargement occurs in 50% of subjects and thyrotoxicosis in 6%. Hirsutism occurs in 24% of women and galactorrhea in 10%.

Diagnosis

Clinical suspicion should be raised by symptoms and signs. Figure 39.10 indicates appropriate tests. Elevated plasma GH, especially in response to an oral glucose tolerance test, is strongly suggestive of the diagnosis. Visual field assessment and MRI of the pituitary fossa are necessary to define the tumor and to exclude supratentorial extension. Most patients with acromegaly have a GH-secreting pituitary adenoma. Rarely, pancreatic or

Figure 39.10 Tests for acromegaly.

hypothalamic tumors release GH-releasing hormone with secondary GH excess. Breast and bronchial tumors can also produce GH.

Treatment

Transsphenoidal adenomectomy is the treatment of choice. Irradiation and drug therapy are valuable when complete removal of tumor tissue is not possible (one third of cases) and when surgery is contraindicated. Dopaminergic agents, such as bromocriptine and cabergoline, and the somatostatin analogue octreotide reduce plasma GH in acromegaly. Bromocriptine may induce tumor shrinkage and improve diabetes. Radiation therapy may not exert its full effect for months or years. Hypopituitarism may occur late after treatment and necessitate endocrine replacement for ACTH, thyroid-stimulating hormone (TSH), or gonadotropin deficiency. Hence, regular monitoring of pituitary function is required after treatment.

Management of Hypertension in Acromegaly

Surgical removal of the pituitary adenoma with normalization of GH levels may reduce blood pressure to some extent, but the majority of patients will continue to require antihypertensive therapy.

Antihypertensive treatment requires a diuretic, given the volume-expanded state. Additional antihypertensive agents are frequently required, and both calcium channel blockers and ACE inhibitors may be effective. β -Blockers may also be used, although theoretically such agents may increase GH hormone concentration.

HYPOTHYROIDISM

Definition and Epidemiology

Hypothyroidism results from deficient production of thyroid hormones, whether through inadequate TSH secretion (from hypothalamic or pituitary lesions) or by impaired functioning of the thyroid itself (loss or atrophy of the gland, autoimmune destruction, iodine deficiency, antithyroid agents, or hereditary defects in hormone synthesis).²⁹ It is estimated that hypertension is 1.5 to 2 times more common in hypothyroid patients than in the general population.³⁰

The pathogenesis of the hypertension is multifactorial and associated with both increased total body sodium and increased peripheral vascular resistance. Even within euthyroid subjects, serum free thyroxine index (FTI) is lower and TSH is higher in hypertensive than in normotensive subjects, and FTI also independently predicts the blood pressure response to increments in dietary sodium in both normotensive and hypertensive subjects.³¹ Hypothyroidism is associated with increased aortic stiffness, which is reversed by hormone replacement therapy.³² Observations of short-term hypothyroidism have confirmed increases in arterial pressure, plasma catecholamines, aldosterone, and cortisol, all reversible with thyroid hormone treatment.³³ The relationship between plasma catecholamine levels and blood pressure is steepened in hypothyroidism. The catecholamine levels of hypothyroid subjects also show more variability associated with more variability in blood pressure. This suggests underdamping of swings in sympathetic activity in the hypothyroid state.³⁴ Hypertension develops despite a low cardiac output. Thyroid replacement therapy corrects the electrolyte,

Figure 39.11 Hypothyroid facies.

hemodynamic, and hormone changes and cures the hypertension in most patients.

Clinical Features

Any organ system can be affected in primary hypothyroidism. Symptoms and signs can be protean. The onset of clinical abnormalities is usually gradual, and diagnosis may not be made until gross hypothyroidism is established. Common clinical features include weakness, dry skin, lethargy, slow slurred speech, sensitivity to cold, thick tongue, facial puffiness (Fig. 39.11), coarse hair, failing memory, constipation, and weight gain with reduced appetite. Coronary heart disease is common, with contributions from dyslipidemia and hypertension accelerating the atherogenic process.

Diagnosis

Hypothyroidism should be considered in any patient with hypertension. Because the clinical manifestations of hypothyroidism are often difficult to elicit, especially in the elderly, thyroid function tests, including TSH when FTI is equivocal, should be performed. In patients with primary hypothyroidism in whom normotension is not achieved by full thyroxine replacement therapy, it is likely that primary hypertension is a concomitant disorder. For those with gross or long-standing hypothyroidism, replacement thyroxine therapy should be cautious to minimize the chances of exacerbating myocardial ischemia.

HYPERTHYROIDISM

Definition and Epidemiology

Hyperthyroidism and thyrotoxicosis may result from Graves' disease and less commonly toxic multinodular goiter, toxic adenoma, high iodine intake, trophoblastic tumor, and (rarely) excessive pituitary TSH secretion. Hypertension is common in hyperthyroidism, with a prevalence of 60% in toxic adenoma and approximately 30% in Graves' disease.

Clinical Features

The clinical features depend on the underlying cause of the hyperthyroidism, severity of the disorder, rapidity of onset, age of the patient, and concomitant disease. Abnormalities may be evident in the cardiovascular system (tachyarrhythmias, heart failure), skin (increased sweating, increasing pigmentation with vitiligo), eyes (lid lag, exophthalmos), nervous system (hypertension, nervousness), alimentary system (increased appetite yet weight loss, diarrhea), and muscles (proximal weakness).

Hypertension in hyperthyroidism is associated with elevated systolic blood pressure and normal or low diastolic pressure. It may be observed in both postpartum thyrotoxicosis and neonatal thyrotoxicosis. Elevation of diastolic pressure is unusual unless there is concomitant primary hypertension.

The hemodynamic characteristics in hypertension of thyrotoxicosis are an increased cardiac output, increased myocardial contractility, tachycardia, decreased peripheral vascular resistance, and expanded blood volume. These indices return to normal in most patients on achieving the euthyroid state. Interestingly, catecholamine levels tend to be low (inversely to hypothyroid hypertension), and there is no heightened activity of the sympathetic system. The renin-angiotensin system (RAS) tends to be activated and the aldosterone levels increased in hyperthyroidism, and this may contribute to the development of systolic hypertension.

Suspicion of hyperthyroidism should be high in the elderly patient with hypertension and a high pulse pressure, particularly if there is also atrial fibrillation. Such patients are liable to develop cardiac failure, in which case the increased systolic arterial pressure will diminish, masking previous hypertension. Hypertension with a high pulse pressure, although typical of hyperthyroidism, is observed in many elderly primary hypertensives because of the loss of the compliance of the aorta with aging.

Diagnosis and Treatment

Diagnosis of hyperthyroidism is confirmed by thyroid function tests, including measurement of TSH. β -Blockers are often effective first-line therapy for hyperthyroidism-associated hypertension. Treatment of hyperthyroidism, whether by antithyroid drugs, surgery, or radioiodine, will often normalize the increased systolic arterial pressure, although this is by no means invariable in the elderly, in whom there may be concomitant primary hypertension.

Neurogenic Hypertension, Including Hypertension Associated with Stroke or Spinal Cord Injury

Venkatesh Aiyagari, Sean Ruland, Philip B. Gorelick

An intimate relationship exists between the nervous system and blood pressure (BP).¹ The role of the sympathetic nervous system in both the short- and long-term regulation of BP is becoming increasingly appreciated. The sympathetic nervous system also has an important role in hypertension after neurologic injury. In this chapter, we discuss the physiology and management of hypertension in such injury.

PHYSIOLOGY AND PATHOPHYSIOLOGY

Neural Control of Blood Pressure

The brainstem, especially the ventral medulla, has a key role in the maintenance of BP (Fig. 40.1). BP is controlled by the nucleus tractus solitarius, which receives inhibitory baroreceptor afferents, and the rostral ventrolateral medulla and rostral ventromedial medulla, which are the source of excitatory descending bulbospinal pressor pathways. In addition, a depressor center in the caudal ventrolateral medulla composed of γ -aminobutyric acid (GABA)-containing neurons receives afferents from the nucleus tractus solitarius and projects to the rostral ventral medulla. These inhibitory GABA-containing neurons are tonically active, and reduced activity of these neurons leads to hypertension.²⁻⁴

The ultimate effector units are the sympathetic neurons located in the intermediolateral cell column of the spinal cord and the parasympathetic neurons found in the dorsal motor nucleus of the vagus and nucleus ambiguus located in the medulla. In addition, impulses from the limbic system, cerebral cortex, and hypothalamus also directly or indirectly project to the intermediolateral cell column of the spinal cord and influence BP regulation.

Cerebrovascular Autoregulation

Under normal conditions, cerebral blood flow (CBF) of the adult brain is 50 ml/100 g/min. CBF is regulated by the relationship between cerebral perfusion pressure (CPP) and cerebrovascular resistance (CVR):

$$\text{CBF} = \text{CPP}/\text{CVR}$$

Cerebral perfusion pressure is defined as the difference between the mean arterial blood pressure (MAP) and the intracranial pressure (ICP). If ICP is increased, systemic BP needs to be higher to maintain CPP and CBF.

Cerebrovascular autoregulation maintains a constant blood flow over a wide range of CPP. Normally, changes in CPP have little effect on CBF because of compensatory changes in CVR. An increase in CPP produces vasoconstriction and a decrease produces vasodilation, thus keeping the CBF constant (Fig. 40.2). Autoregulation is effective for a range of CPP from about 60 to 150 mm Hg. In chronically hypertensive individuals, the cerebral arterioles develop medial hypertrophy and lose the ability to dilate effectively at lower pressures. This leads to a shift of the autoregulatory curve to the right.⁵ In these individuals, a rapid reduction of BP may lead to a drop in CBF even though the BP might still be within the “normal” range. With effective control of hypertension for several months, the normal range for autoregulation can be reestablished.⁶

Above the upper limit of autoregulation, there is breakthrough vasodilation leading to damage of the blood-brain barrier and cerebral edema and possibly cerebral hemorrhage. Below the lower limit of autoregulation, decreases in CPP lead to a decrease in CBF. Under these circumstances, increased extraction of oxygen and glucose maintains normal cerebral metabolism and brain function. When the CBF decreases to less than 20 ml/100 g/min, the increase in oxygen extraction is no longer able to supply the metabolic needs of the brain, leading to impairment of brain function.

SPECIFIC SYNDROMES

Hypertension After Stroke

Epidemiology

Hypertension is the most important modifiable risk factor for stroke, and reduction in BP is effective in the primary prevention of stroke, improves outcomes in patients who have had an ischemic stroke, and may be especially beneficial for lowering risk of stroke among those with a history of intracerebral brain hemorrhage.⁷ Combined data from 40 trials of antihypertensive agents have demonstrated that a 10% reduction in systolic blood pressure (SBP) lowers stroke risk by one third.⁸ A 5-mm lower diastolic pressure together with a 9-mm lower systolic pressure confers a 33% lower risk of stroke, and a 10-mm lower diastolic pressure together with an 18- to 19-mm lower systolic pressure confers more than a 50% reduction in stroke risk.⁹ In patients who have had a stroke, the Perindopril Protection Against Recurrent Stroke Study (PROGRESS) showed that a reduction of BP was associated with a significant reduction of total stroke recurrence by 28% and a reduction of major coronary

Figure 40.1 Neural pathways involved in the control of blood pressure. The ventral medulla has a key role in generating both excitatory (solid line) and inhibitory (dotted line) pathways, largely through the rostral ventrolateral medullary neurons (RVLM) and nucleus tractus solitarius (NTS), respectively. Ultimate effector control is provided by sympathetic activation originating in the intermediolateral cell column (IMLC) and parasympathetic action through the nucleus ambiguus (NA) and dorsal motor nucleus of the vagus nerve (DMV). CVLM, caudal ventrolateral medullary neurons.

and vascular events by 26%, even in subjects with a normal initial BP.¹⁰

However, the management of BP in the immediate aftermath of a stroke is controversial.¹¹ A high proportion of patients have elevated BP immediately after a stroke, and BP has been shown to spontaneously decrease during 1 to 2 weeks to the prestroke baseline in most patients. Some of the postulated causes of elevated BP are listed in Figure 40.3. An increased BP after stroke is associated with a higher mortality. Nonetheless, it is uncertain whether the increased BP directly contributes to poor outcome and whether immediate lowering of BP will lead to better outcomes.

Pathophysiology

An understanding of cerebrovascular pathophysiology is essential to understand the pros and cons of treating hypertension in these patients (Fig. 40.4).

In patients with an ischemic stroke, vascular occlusion leads to a central region of irreversibly ischemic brain surrounded by an ischemic zone where blood flow is reduced but brain tissue is

still viable. After 2 or 3 days, the ischemic areas either recover completely or undergo infarction. In the first few days, perfusion in this zone is marginal, and a further decrease in blood flow might lead to infarction. Because cerebral autoregulation is impaired with acute ischemic stroke, a fall in BP could lower blood flow and extend infarction, and a very high BP could lead to hemorrhagic transformation, especially if thrombolytic agents have been given.

At times, it can be difficult to distinguish between hypertensive encephalopathy, in which lowering of BP is clearly indicated, and ischemic stroke with hypertension. The level of consciousness, the presence of focal neurologic deficits, and the fundoscopic examination can help in making this distinction. Hypertensive encephalopathy is a syndrome of global neurologic dysfunction, usually with papilledema, and focal neurologic deficits are usually less prominent. In acute ischemic stroke, the focal neurologic deficit is more prominent, and alterations of consciousness are less common except with brainstem strokes or when there is “malignant” brain edema due to a massive hemispheric infarction.

Figure 40.2 Cerebral autoregulation curve. In the normal state (solid line), the CBF is held constant across a wide range of CPP (60 to 150 mm Hg). In chronic hypertension (dashed line), the autoregulation curve shifts to the right. In the presence of acute cerebral ischemia (dotted line), cerebral autoregulation may be impaired, and the CBF becomes dependent on the CPP. CBF, cerebral blood flow; CPP, cerebral perfusion pressure; CVR, cerebral vascular resistance; ICP, intracranial pressure; JVP, jugular venous pressure; MAP, mean arterial pressure. Postulated Causes of Hypertension After Stroke

Preexisting hypertension
White coat effect
Stress of hospitalization
Cushing reflex*
Catecholamine and cortisol release
Lesion of brainstem or hypothalamus
Nonspecific response to brain damage

Figure 40.3 Postulated causes of hypertension after stroke. *A hypothalamic response to raised intracranial pressure or ischemia consisting of hypertension with bradycardia.

In patients with intracerebral hemorrhage (ICH), the considerations are different. Hematoma expansion occurs in one third of patients with ICH in the first 24 hours.¹³ Therefore, BP is often lowered in these patients in the hope that this might decrease hematoma expansion. However, the evidence does not support a clear association between high BP and hematoma expansion.¹⁴ On the other hand, some patients with ICH might have increased ICP due to the hematoma volume or associated hydrocephalus. In such a situation, lowering of BP is not warranted as it might critically lower CPP. Monitoring of ICP and CPP may be helpful in these circumstances.

In patients with aneurysmal subarachnoid hemorrhage (SAH), there is a significant risk of rebleeding; tight BP control is recommended to decrease the rebleeding risk. Some patients with SAH have associated myocardial dysfunction (“stunned myocardium”),

Pros and Cons of Acute Treatment of Hypertension in Stroke

	Pros	Cons
Acute ischemic stroke	<ul style="list-style-type: none"> Might lower mortality Might decrease stroke progression Might decrease hemorrhagic transformation (especially after t-PA) Might decrease cerebral edema formation Might be helpful for systemic reasons (e.g., associated myocardial ischemia) Patients likely to be more compliant with antihypertensive use if treatment is initiated in the hospital 	<ul style="list-style-type: none"> Decreases on its own No proven benefit Ongoing ischemia around the infarct (ischemic penumbra) Altered autoregulation due to chronic hypertension, ischemia Large-vessel stenosis might have resulted in reduction of perfusion Chance of propagating thrombus Anecdotal case reports and trial results demonstrating deterioration with decrease in blood pressure Principle of do no harm (<i>primum non nocere</i>)
Acute intracerebral hemorrhage	<ul style="list-style-type: none"> Might lower mortality Might decrease hematoma expansion Might decrease cerebral edema formation Might be helpful for systemic reasons (e.g., associated myocardial ischemia) Patients likely to be more compliant with antihypertensive use if treatment is initiated in the hospital 	<ul style="list-style-type: none"> Decreases on its own No proven benefit There may be a zone of ischemia around an intracerebral hematoma Chronically hypertensive patients require higher perfusion pressure due to shift of autoregulatory curve ICP may be elevated and lowering BP reduces what could be marginal CPP Principle of do no harm (<i>primum non nocere</i>)
Aneurysmal subarachnoid hemorrhage	<ul style="list-style-type: none"> Might decrease rebleeding rate Might help if there is cardiac ischemia (stunned myocardium) 	<ul style="list-style-type: none"> No proven benefit ICP may be elevated and lowering BP reduces what could be marginal CPP Might lead to cerebral ischemia in the presence of vasospasm

Figure 40.4 Pros and cons of acute treatment of hypertension in stroke. BP, blood pressure; CPP, cerebral perfusion pressure; ICP, intracranial pressure; t-PA, tissue plasminogen activator.

in which case high BP might worsen myocardial function. As described before, in patients with hydrocephalus or an associated ICH, ICP and CPP monitoring can help guide BP management. In the latter half of the first week and in the second week after SAH, many patients develop vasospasm of the intracranial arteries. Reduction of BP may lead to worsening of cerebral ischemia in this situation. Therefore, once the aneurysmal rupture has been adequately treated with surgical clipping or coiling, BP is usually maintained at a normal or slightly elevated level in these patients.

Diagnosis and Treatment

Large studies adequately powered to assess the benefits and risks of BP lowering after ischemic and hemorrhagic stroke have not yet been performed. A recent Cochrane review on this topic concluded that there is insufficient evidence to evaluate the effect of altering BP on outcome during the acute phase of stroke.¹⁵ The available evidence is summarized here.

A broad overview of recommendations for treating BP in different clinical situations is outlined in Figure 40.5.

Acute Ischemic Stroke The Acute Candesartan Cilexetil Evaluation in Stroke Survivors (ACCESS) trial studied early or late treatment with candesartan after a stroke in patients who were

conscious, had a motor paresis, and were hypertensive. The combined endpoint of total mortality, cerebral complications, and cardiovascular complications at the end of 3 months was reduced by 48% for patients treated with candesartan (4 to 16 mg) initiated within 72 hours after stroke compared with those in whom it was instituted 7 days later. However, this difference in outcome was not associated with any difference in BP.¹⁶

In the Controlling Hypertension and Hypotension Immediately Post-Stroke (CHHIPS) trial, hypertensive patients with an ischemic or hemorrhagic stroke were randomized within the first 36 hours to labetalol, lisinopril, or placebo, titrated to a systolic BP goal of 145 to 155 mm Hg or a systolic BP reduction of 15 mm Hg from the BP at randomization. The primary outcome of death or dependency at 2 weeks in the treated group was not significantly different from that of the placebo group; however, mortality was halved at 3 months in the treatment groups compared with placebo.¹⁷

Early decrease in BP had no effect on outcome in the Glycine Antagonist in Neuroprotection (GAIN Americas) trial. In the Intravenous Nimodipine West European Stroke Trial (INWEST), a more than 20% reduction of diastolic BP on day 2 was associated with a worse outcome.^{18,19}

The currently recommended guidelines of the American Heart Association/American Stroke Association and the European Stroke Organization for BP management in acute ischemic stroke are summarized in Figure 40.6.^{20,21}

Intracerebral Hemorrhage A small controlled study of 14 hypertensive patients with a small- to moderate-sized ICH within 24 hours showed that treatment with nicardipine or labetalol to reduce MAP by 15% to a lower MAP limit of ~120 mm Hg produced no change in cerebral blood flow.²² In contrast, a decrease in MAP by more than 20% or a SBP below 110 mm Hg in patients with ICH has been shown to lower blood flow.²³

The Antihypertensive Treatment in Acute Cerebral Hemorrhage (ATACH) study used intravenous nicardipine infusion for 18 to 24 hours in patients with ICH with a SBP above 200 mm Hg presenting within 6 hours of symptoms. Patients with small hematomas (mean volume <20 ml) were treated to three different SBP goals (170 to 200, 140 to 170, and 110 to 140 mm Hg) with no difference in 3-month mortality between the groups.²⁴

The Intensive Blood Pressure Reduction in Acute Cerebral Hemorrhage Trial (INTERACT) randomized hypertensive patients within 6 hours of symptom onset to achieve a target of

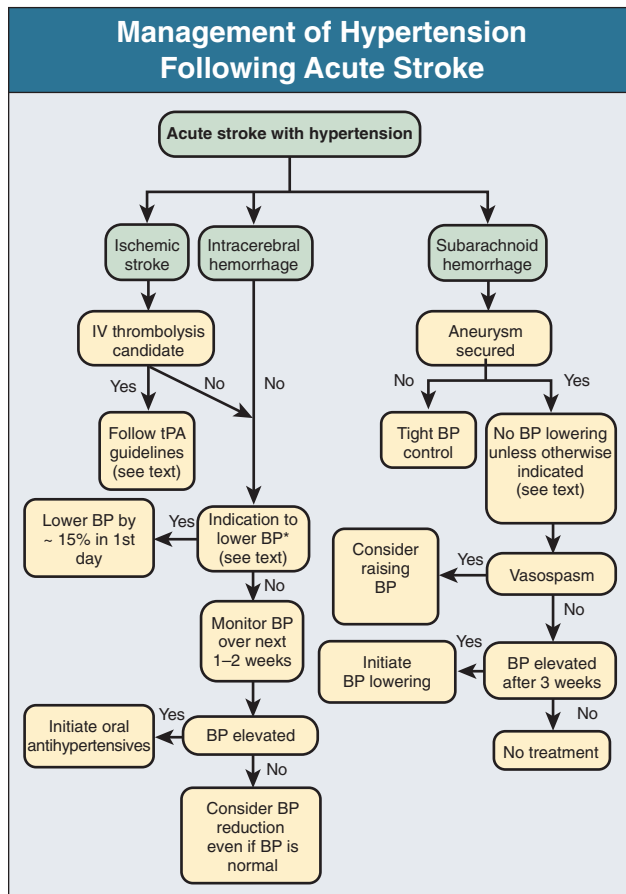

Figure 40.5 Management of hypertension after acute stroke. BP, blood pressure; t-PA, tissue plasminogen activator. *Indication for treatment includes systolic BP above 220 mm Hg or diastolic BP above 120 mm Hg for ischemic stroke, the presence of associated conditions such as aortic dissection or myocardial infarction, and, in cases of cerebral hemorrhage, systolic BP above 180 mm Hg or mean arterial pressure above 130 mm Hg.

<ul style="list-style-type: none"> • If SBP is >200 mmHg or MAP is >150 mm Hg, then consider aggressive reduction of blood pressure • If SBP is >180 mmHg or MAP is >130 mmHg and there is evidence of or suspicion of elevated ICP, then consider monitoring ICP and reducing blood pressure to keep cerebral perfusion pressure > 60 to 80 mm Hg • If SBP is >180 mm Hg or MAP is >130 mm Hg and there is not evidence of or suspicion of elevated ICP, then consider a modest reduction of blood pressure (e.g., MAP of 110 mm Hg target blood pressure of 160/90 mm Hg) 	<ul style="list-style-type: none"> • Routine BP lowering is not recommended • Treatment is recommended in: <ul style="list-style-type: none"> • Patients with known history of hypertension or signs (ECG, retina) of chronic hypertension: SBP >180 mmHg or DBP >105 mm Hg. If treated, target blood pressure should be 170/100 mm Hg (or a MAP of 125 mm Hg) • Patients without known hypertension: SBP >160 mm Hg and/or DBP >95 mm Hg. If treated, target blood pressure should be 150/90 mm Hg (or a MAP of 110 mm Hg) • A reduction of MAP by >20% should be avoided • These limits and targets should be adapted to higher values in patients undergoing monitoring of increased ICP, to guarantee a sufficient CPP >70 mm Hg

140 or 180 mm Hg. Treatment was for 7 days or until hospital discharge. The lower BP target resulted in less hematoma expansion at 24 hours, but this difference was not significant after adjustment for initial hematoma volume and time from onset of ICH to computed tomographic CT scan. There was no significant difference in adverse event rate or outcome at 90 days.²⁵

Although neither ATACH nor INTERACT was powered to detect a difference in clinical outcome, the results indicate that acute BP reduction in ICH may be safe.

The currently recommended guidelines of the American Heart Association/American Stroke Association and the European Stroke Initiative for BP management in acute ICH are summarized in Figure 40.7.^{26,27}

Subarachnoid Hemorrhage Before definitive treatment of the ruptured aneurysm, SBP is usually kept below 140 to 160 mm Hg, although there is no conclusive evidence that higher BPs increase rebleeding rate. In patients with suspected elevation of ICP, it is important to monitor ICP and to keep the CPP above 70 mm Hg. The recently published American Heart Association/American Stroke Association guidelines recommend monitoring and control of BP to balance the risk of stroke, hypertension-related bleeding, and maintenance of CPP, but no absolute treatment thresholds or goals are specified.²⁸ After the ruptured aneurysm has been secured, aggressive treatment of BP should be avoided, and in the setting of cerebral vasospasm, BP is usually elevated until the neurologic deficits resolve, generally up to a SBP of 200 to 220 mm Hg.

Hypertension After Carotid Endarterectomy and Endovascular Procedures

Definition and Epidemiology

Hemodynamic disturbances such as hypotension, bradycardia, and hypertension are common (10% to 40%) after carotid endarterectomy and endovascular procedures such as angioplasty and stenting. In addition, 10% of patients develop the “carotid hyperperfusion (or reperfusion) syndrome.” This syndrome occurs in the first week after surgery or angioplasty-stenting and is manifested as transient or permanent contralateral neurologic signs, ipsilateral pulsatile headache, seizures, ICH, or reversible cerebral edema.^{29–31} Some subjects with post-revascularization cerebral

hyperperfusion may not manifest clinical signs acutely but may later develop cortical neuronal loss and cognitive impairment.³²

Pathophysiology

Preexisting hypertension, baroreceptor impairment after surgical manipulation, and elevated catecholamine levels after cerebral hypoperfusion during intraoperative cross-clamping may contribute to postoperative hypertension that contributes to cerebral hyperperfusion. The hyperperfusion syndrome may be due, in part, to impaired autoregulation from chronic vasodilation of the distal vascular bed ipsilateral to a hemodynamically significant internal carotid artery stenosis.³³ Other postulated mechanisms include activation of the trigeminovascular axon reflex and derangement of the carotid baroreceptors.³⁴

Diagnosis and Treatment

Cerebral hyperperfusion is defined as a postoperative increase in CBF of more than 100% compared with preoperative flow. However, this increase in blood flow may be only approximately 20% compared with the contralateral side.³⁵ Subjects at risk for development of this syndrome are those with extensive microvascular disease, preoperative hypoperfusion and impaired autoregulation, or postoperative hyperperfusion.

Because of the risk for development of carotid hyperperfusion syndrome after carotid endarterectomy or stenting, all patients should have continuous intraoperative and postoperative BP monitoring. Most authors advocate strict BP control (SBP <120 mm Hg) from the time of intraoperative internal carotid artery unclamping or angioplasty, particularly in high-risk subjects.³⁶ Elevated BP should be treated with intravenous labetalol or clonidine. Vasodilators such as nitroglycerin and sodium nitroprusside should be avoided.

Hypertension After Spinal Cord Injury

Definition and Epidemiology

Autonomic dysreflexia occurs in up to 70% of subjects after spinal injury. It is defined as an increase in SBP by at least 20%, associated with a change in heart rate and accompanied by at least one sign (sweating, piloerection, facial flushing) or symptom (headache, blurred vision, stuffy nose).³⁷ If it is unrecognized, it can result in serious sequelae, such as posterior

leukoencephalopathy, ICH, SAH, seizures, arrhythmia, pulmonary edema, retinal hemorrhage, and rarely coma or death.³⁸

Pathophysiology and Diagnosis

The spinal cord lesion is typically at or above the sixth thoracic spinal nerve level. Immediately after the injury, there is initial loss of supraspinal sympathetic control similar to the initial period of muscle flaccidity. This often leads to hypotension and bradycardia (spinal shock). After a few weeks to months, there is extrajunctional sprouting of the α -receptors, denervation hypersensitivity, and impaired presynaptic uptake of norepinephrine. In addition, there may be derangement of spinal glutaminergic interneurons. Noxious stimuli below the neurologic level of the lesion trigger a spinal reflex arc that results in increased sympathetic tone and hypertension.³⁹ The most common inciting events are urinary overdistention and fecal impaction. However, it may be secondary to precipitants including sympathomimetic medications and sildenafil citrate used for sperm retrieval.⁴⁰

Clinical symptoms include pulsatile headache, blurred vision, nasal congestion, nausea, and sweating above the spinal nerve level. The flushed sweaty skin above the lesion level is due to brainstem parasympathetic activation. At and below the lesion, the skin remains pale, cool, and dry. Heart rate can be quite variable from bradycardia to tachycardia. The hallmark physical finding is elevated BP. However, as BP may normally be quite low after spinal cord injury, baseline BP readings may be within the normal range but elevated for a given individual, making clinical suspicion and reliance on other clinical signs and symptoms paramount in the diagnosis if baseline BP is not known.³⁹

Treatment

Vigilant preventive measures for autonomic dysreflexia include proper bowel, bladder, and skin care. However, expeditious treatment of elevated BP is critical to avoid the potentially severe consequences. Placement of the patient upright to precipitate orthostatic BP lowering and removal of any possible noxious

stimuli, such as binding clothing and devices, are the initial treatment steps. Checking for fecal impaction and urinary overdistention and changing, flushing, or insertion of a new catheter if the patient receives intermittent catheterization are important.

Pharmacologic treatment with rapid-acting, short-lived agents may be indicated for SBP elevation of 150 mm Hg or more that persists after the preceding interventions. To avoid precipitating hypotension, nitrate-containing agents should not be given for 24 hours before the use of sildenafil or similar agents. If the bladder is empty and the BP is below 150 mm Hg, fecal disimpaction with topical anesthetic should be attempted. If dysreflexia is refractory or associated with severe clinical presentation, other precipitants should be sought and hospitalization may be indicated.⁴¹

Up to 90% of pregnant women with upper spinal cord injury experience autonomic dysreflexia during labor and delivery. Appropriate epidural or spinal anesthesia techniques can ameliorate the risk.⁴²

Cerebrovascular Effects of Antihypertensive Agents

Different classes of antihypertensive agents have different direct effects on the CBF, ICP, and autoregulation. The ideal drug would not increase ICP or decrease blood flow to ischemic regions. In addition, in treatment of hypertension in the acute setting, drugs that can be given intravenously, have a short half-life, and do not cause sedation are preferable. In the chronic phase after a stroke, there is no clear evidence favoring one class of antihypertensive agent over another.

The advantages and disadvantages of various classes of antihypertensive agents in the acute stroke setting are summarized in Figure 40.8.

β -Adrenergic antagonists (e.g., esmolol) and combined α - and β -adrenergic receptor antagonists (e.g., labetalol) do not increase ICP or affect cerebral autoregulation. They are suitable for treatment of hypertension in the setting of cerebral ischemia or

Preferred Antihypertensive Agents in the Treatment of Stroke-Associated Hypertension				
Drug	Mechanism of Action	Intravenous Dose	Advantages	Disadvantages
Labetalol	α_1 -, β_1 -, and β_2 -receptor antagonist	Test dose 5 mg, then 20- to 80-mg bolus every 10 min up to 300 mg; IV infusion 0.5–2 mg/min	Does not lower CBF Does not increase ICP	May exacerbate bradycardia
Esmolol	β_1 -receptor antagonist	500- μ g/kg bolus, then 50–300 mg/kg/min	Does not lower CBF Does not increase ICP	May exacerbate bradycardia
Sodium nitroprusside	Vasodilator	0.25–10 μ g/kg/min	Potent antihypertensive	May increase ICP Can cause cerebral steal Potential for cyanide toxicity
Nitroglycerin	Vasodilator	5–100 μ g/kg/min	Can be helpful for concomitant cardiac ischemia	May increase ICP Can cause cerebral steal
Hydralazine	Vasodilator	2.5- to 10-mg bolus	Can be given as IV bolus when labetalol is contraindicated due to bradycardia	May increase ICP Can cause cerebral steal
Nicardipine	L-type CCB	5–15 mg/h	Does not decrease CBF	May increase ICP Long duration of action
Enalaprilat	ACE inhibitor	0.625–1.25 mg every 6 hr	Does not decrease CBF	Variable response Long duration of action

Figure 40.8 Preferred antihypertensive agents in the treatment of stroke-associated hypertension. ACE, angiotensin-converting enzyme; CBF, cerebral blood flow; CCB, calcium channel blocker; ICP, intracranial pressure.

increased ICP. However, bradycardia secondary to increased ICP is a relative contraindication.

Vasodilators (e.g., hydralazine, sodium nitroprusside, nitroglycerin) cause cerebral arterial dilation and venodilation and can theoretically increase ICP and cause a cerebral steal phenomenon in patients with cerebral ischemia. However, they may be used in patients with small and moderate-sized ICH and in patients with SAH if increased ICP is not a concern.

Calcium channel blockers (CCB) have varying effects on cerebral autoregulation. Nifedipine can lead to severe reduction in BP and is not recommended. Nimodipine is used routinely in patients with SAH as it has been shown to improve outcome, possibly due to a neuroprotective effect. Nicardipine has been used in patients with acute ICH without any change in CBF and is often used in patients with SAH.

Angiotensin-converting enzyme (ACE) inhibitors and the angiotensin receptor blocker (ARB) candesartan have been used in patients with cerebral ischemia and have no effect on CBF. However, short-acting parenteral forms of these drugs are not available. ACE inhibitors and ARBs shift the lower limit of cerebral autoregulation toward lower BP in rats and humans. However, these agents have a long half-life, which is not desirable in treatment of hypertension in the acute phase.

Similarly, because of its long half-life and sedative effect, the α_2 -adrenergic agonist clonidine is not preferred.

Renal Physiology in Normal Pregnancy

Chris Baylis, John M. Davison

There are profound changes in renal function in normal pregnancy that lead to marked alterations from the nonpregnant physiologic norm. An appreciation and understanding of these alterations are essential to recognize both normal and compromised pregnancies.

ANATOMY

The kidneys increase 1 to 2 cm in length and in volume by up to 70% in normal pregnancy because of increases in both vascular and interstitial fluid compartments. The most striking anatomic change is dilation of the calyces, renal pelvis, and ureter (more prominent on the right side), and by the third trimester, about 80% of women show evidence of hydronephrosis (Fig. 41.1).¹ A consequence of the ureteral dilation is urinary stasis, which predisposes pregnant women with asymptomatic bacteriuria to development of symptomatic ascending infection (acute pyelonephritis). Rarely, the anatomic changes may be extreme and precipitate the overdilatation syndrome, with massive dilation, recurrent severe flank pain, increasing serum creatinine, hypertension, or even reversible acute kidney injury.²

SYSTEMIC HEMODYNAMICS

There are significant alterations in systemic hemodynamics in normal pregnancy. A plasma (and extracellular fluid) volume expansion occurs while red cell volume also increases, leading to a large increase in blood volume that correlates with clinical outcome and birth weight. Interestingly, subsequent pregnancies tend to be more successful than the first, with bigger babies and larger plasma volume increases. Women with twins and triplets have proportionately greater increments, and those with poorly growing fetuses, as in preeclampsia or when there is a history of poor reproductive performance, have correspondingly poor plasma volume responses. The increase in plasma volume (maximum increase ~1.25 liters) takes place progressively up to 32 to 34 weeks, after which there is little further change. The plasma volume expansion has a hemodilutional effect, causing decreases in hematocrit: the physiologic anemia of normal pregnancy.³

Cardiac output is significantly increased by the fifth gestational week, initially caused by a 10% to 20% increase in heart rate (80 to 90 beats per minute), with stroke volume increased by more than 20% the eighth week. Cardiac output increases of 40% to 50% are well established by the 24th week. Left atrial and left ventricular end-diastolic dimensions increase, suggesting an associated increase in venous return. There is also a progres-

sive increase in aortic valve orifice area. Despite the 40% to 50% increase in cardiac output, systemic blood pressure substantially decreases in normal pregnancy (representative values are shown in Figs. 41.2 and 41.3).⁴ The physiologic decrease in blood pressure results from a profound reduction in systemic vascular resistance of unknown cause, although the loss of responsiveness to vasoconstrictor agents (e.g., angiotensin II, arginine vasopressin) certainly contributes.⁵ Inhibition of angiogenic factors in preeclampsia causes vasoconstriction, suggesting that these factors, such as vascular endothelial growth factor, may contribute importantly to normal gestational vasodilation through stimulation of endothelial nitric oxide and prostaglandins.⁶ The combination of increased cardiac output and peripheral vasodilation means that organ blood flow increases in pregnancy, with the most dramatic changes occurring in the kidney and skin circulation throughout gestation and in the uterus in the second part of the pregnancy.⁴ In the third trimester, the enlarged uterus compresses surrounding tissues and can influence hemodynamic measurements, so that attention should be paid to maternal posture during hemodynamic monitoring. In the supine position, there is partial obstruction of the inferior vena cava and decreased venous return, reducing cardiac output and causing a decrease in blood pressure, the supine hypotensive syndrome of pregnancy. It is important to be aware of these postural effects in measuring blood pressure in late pregnancy.⁴

RENAL HEMODYNAMICS

There are striking changes in renal hemodynamics in normal pregnancy, with an increase in glomerular filtration rate (GFR) and consequent decrease in serum creatinine detectable very early.⁷ The GFR increases ~25% by 4 weeks after the last menstrual period, and a robust early increase in GFR (see Fig. 41.3) is invariably associated with a good obstetric outcome. Longitudinal studies in normal pregnant women show that GFR (measured by inulin or 24-hour creatinine clearance) increases by a maximum of ~50% by mid-pregnancy, which is maintained until the last few weeks of the pregnancy, when values begin to decrease but remain above the nonpregnant level (Fig. 41.4; see also Fig. 41.2).⁸ These marked increases in GFR mean that serum creatinine decreases to ~0.4 to 0.5 mg/dl (36 to 45 $\mu\text{mol/l}$),⁹ and values considered normal for nonpregnant conditions of 0.7 to 0.8 mg/dl (63 to 72 $\mu\text{mol/l}$) are a cause for concern in normal pregnancy (see Fig. 41.3). The increase in renal plasma flow (RPF) of ~60% is slightly more pronounced than the increase in GFR (see Fig. 41.2), so that the filtration fraction (FF) decreases (see later discussion). At the end of pregnancy, the RPF decreases

Figure 41.1 Hydronephrosis in normal pregnancy. Intravenous urogram at 36 weeks' gestation. Note bilateral hydronephrosis, more marked on the right side.

Changes in Some Common Indices During Pregnancy		
	Nonpregnant	Pregnant
Hematocrit (%)	41	33
Plasma protein (g/dl)	7.0	6.0
Plasma osmolality (mOsm/kg)	285	275
Plasma sodium (mmol/l)	140	135
Plasma creatinine (mg/dl, μ mol/l)	0.8 (73)	0.5 (45)
Blood urea nitrogen (mg/dl)	12.7	9.3
Plasma urea (mmol/l)	4.5	3.3
pH units	7.40	7.44
Arterial PCO ₂ (mm Hg)	40	30
Plasma bicarbonate (mmol/l)	25	20
Plasma uric acid (mg/dl, μ mol/l)	4.0 (240)	3.2 (190) early 4.3 (260) late
Systolic BP (mm Hg)	115	105
Diastolic BP (mm Hg)	70	60

Figure 41.3 Changes in some common indices during pregnancy. BP, blood pressure. (Mean values compiled from references 7-9, 16, 27.)

Figure 41.2 Hemodynamic alterations induced by normal pregnancy. Increments and decrements in hemodynamic and biochemical parameters shown as percentage of change from nonpregnant baseline. ERPf, effective renal plasma flow; GFR, glomerular filtration rate; NP, nonpregnant; SVR, systemic vascular resistance.

Figure 41.4 Renal function in early pregnancy. Changes in 24-hour creatinine clearance measured weekly before conception and through pregnancy. There was uncomplicated spontaneous abortion in two women (red and green colored lines). The blue line represents the mean and the yellow area shows the range for nine women with successful obstetric outcome. LMP, last menstrual period; MP, menstrual period. (Modified from references 7, 8, and 16.)

proportionally more than the GFR, so that FF increases to the nonpregnant value.^{8,10}

A similar pattern of renal hemodynamic change occurs during pregnancy in some animals, including the rat, in which GFR increases to a maximum of 30% to 40% above the virgin value by midterm, with a late return toward the nonpregnant value

close to term (22 days). Glomerular micropuncture studies have shown that the increase in GFR is paralleled by increases in single-nephron GFR secondary to increased glomerular plasma flow.¹¹ Because the preglomerular and postglomerular resistance vessels dilate in parallel, glomerular plasma flow increases without a change in glomerular blood pressure. As shown in Figure 41.5, the glomerular blood pressure remains unchanged throughout the pregnancy despite marked alterations in preglomerular vascular resistance. Similar conclusions have been reached by an indirect modeling approach in normal pregnant

Figure 41.5 Glomerular hemodynamics in normal pregnancy in the rat. Summary of mean glomerular capillary blood pressure (P_{GC} , upper panel) and preglomerular arteriolar resistance (R_A , lower panel) in Munich Wistar rats in the virgin state (V) and throughout normal pregnancy.^{11,12}

women measuring whole-kidney GFR, RPF, and plasma protein concentrations; in addition, polydisperse neutral dextran was infused for determination of dextran sieving curves.^{7,10} This approach allows (with certain reasonable assumptions) modeling of glomerular hemodynamics. In pregnant women, there is a decrease in plasma protein concentration that contributes slightly to the increased GFR. As in the rat, the majority of the gestational increase in GFR in normal women is due to increased RPF with no change in glomerular blood pressure. The constancy of glomerular blood pressure during sustained renal vasodilation has important implications for the long-term effects of pregnancy on renal function, as discussed later.

It is often assumed that a change in FF reflects a change in glomerular blood pressure, but this is not always the case because FF is also determined by K_f , the product of water permeability of the glomerular wall and total glomerular capillary surface area.⁸ Both glomerular wall water permeability and filtration pressure are very high, and thus filtration proceeds rapidly. In some situations, not all the available filtration surface area is used, so that filtration ceases (because the driving pressure is exhausted) before the end of the glomerulus. This state is known as filtration pressure equilibrium. When plasma flow increases during filtration pressure equilibrium, a proportional increase in GFR occurs with no change in FF. This is seen in the normal pregnant rat.¹¹ In contrast, FF decreases during normal pregnancy in women as RPF is increasing.⁸ Most likely this reflects

the fact that humans are closer than rats to filtration pressure disequilibrium, a situation in which the entire glomerular capillary surface area available for filtration is used, leaving a positive driving pressure at the end of the glomerulus. At filtration pressure disequilibrium, GFR becomes less dependent on plasma flow; thus, an increase in plasma flow (with no change in the other determinants of filtration) leads to a disproportionately smaller increase in GFR, with a decrease in FF (see reference 12 for a fuller explanation).

Despite the prolonged renal vasodilation, the renal vasculature remains fully responsive to various stimuli during pregnancy. For example, in the rat, the intrinsic renal autoregulatory ability remains intact,¹³ and the tubuloglomerular feedback component of renal autoregulation is reset to recognize the elevated GFR as normal.¹⁴ Both pregnant rats and women exhibit a marked additional renal vasodilation in response to amino acid infusion,^{15,16} demonstrating substantial renal vasodilatory reserve in normal pregnancy. The cause of the gestational increase in GFR remains uncertain, although studies in the pseudopregnant rat have shown that the fetoplacental unit is not necessary,¹⁷ indicating that a maternal stimulus must initiate the gestational renal hemodynamic changes. A number of vasoactive factors have been evaluated as possible mediators of the renal vasodilation,¹¹ and although there are no clinical data, animal studies have implicated a role for nitric oxide.¹⁸⁻²⁰ Studies have suggested a key role for the ovarian hormone relaxin, which may signal increased renal nitric oxide production in pregnancy, possibly through an endothelin type B receptor mechanism.^{21,22} The renal vasodilatory signal of pregnancy is remarkably robust because women with single kidneys (organ donors) and renal transplant recipients who have already undergone significant compensatory renal hypertrophy and vasodilation can produce further increases in RPF and GFR in pregnancy.^{7,8} Furthermore, in the human, the signal is not solely relaxin as there is still a gestational increase in GFR, albeit blunted, in infertile women who lack ovarian function and who conceive from ovum donation and assisted conception techniques.²³

Glomerular hypertension associated with renal vasodilation is considered a primary pathogenic stimulus to progressive renal injury in chronic kidney disease.²⁴ As discussed before, normal pregnancy is also a state of chronic renal vasodilation; however, glomerular blood pressure remains normal. This may account for the findings that repetitive pregnancies in women and rats with normal renal function have no long-term adverse effects on glomerular function or structure.²⁵ Pregnancy will increase the rate of loss of renal function in some women with underlying renal disease (see Chapter 43), but the available evidence suggests that this is not by a hemodynamically mediated action.^{7,25}

Formulae that use serum creatinine in relation to age, height, and weight to calculate GFR (e.g., the Cockcroft-Gault formula) should not be used in pregnancy because body weight or size does not reflect kidney size. The use of estimated GFR (eGFR) from the Modification of Diet in Renal Disease (MDRD) study equation, whereby serum creatinine is adjusted for age, gender, and race, cannot be recommended in pregnancy because it significantly underestimates GFR.²⁶

Abnormal Renal Hemodynamics

A woman may lose up to 50% of her renal function and still maintain serum creatinine concentration below 1.5 mg/dl (130 μ mol/l) because of hyperfiltration in remaining nephrons; but if there is more severe compromise, further glomerular

damage will cause serum creatinine to increase.^{7,26,27} Pregnancy in the presence of impaired renal function has a marked adverse effect on obstetric outcome as well as increased risk of an accelerated decline in renal function, as mentioned before (discussed in Chapter 43).²⁸

In preeclampsia, both RPF and GFR decrease, although absolute values may remain above the nonpregnant range. A decrease in ultrafiltration coefficient (K_f) of around 50% in combination with reduced RPF is the most likely mechanism for the hypofiltration.²⁷ The endothelium is targeted at an early stage in preeclampsia and the glomerulus is not spared, with the vascular endothelial cell dysfunction (glomerular endotheliosis) resulting in so-called swollen bloodless glomeruli and the loss of glomerular barrier size and charge selectivities (see Chapter 42). Glomerular endotheliosis is considered by most to be merely characteristic, not pathognomonic, of preeclampsia, whereas others believe this not to be the case because renal biopsy also reveals the lesion in healthy controls,²⁹ but in a study in which there are concerns about qualitative histologic grading as well as ethical issues.³⁰

RENAL TUBULAR FUNCTION IN PREGNANCY

There is an enormous plasma volume expansion in normal pregnancy and resultant small decrements in plasma concentration of many solutes (see Fig. 41.2). Nevertheless, the large increase in GFR means that the filtered load of most plasma constituents will increase during pregnancy.^{7,8} Increments in excretion are seen for some substances, but this is limited by increases in tubular reabsorption, preventing depletion. Intake also often increases, with net retention leading to positive balance for many of the key constituents. The renal handling of a number of solutes is altered in normal pregnancy.

Uric Acid

Uric acid, an endpoint of purine metabolism, is freely filtered at the glomerulus, extensively reabsorbed in the proximal tubule with further downstream reabsorption and possibly some active secretion, such that only ~10% of filtered load is excreted. Plasma uric acid concentration decreases during early pregnancy by ~25% (see Fig. 41.3), which may reflect a decrease in net tubular reabsorption.⁸ As the pregnancy advances, fractional excretion of uric acid decreases, leading to an increasing plasma uric acid concentration, attaining levels close to the nonpregnant mean. Serum uric acid concentrations are significantly higher in preeclamptic pregnancy, and above a critical level of 6 mg/dl (350 μ mol/l), there is excess perinatal mortality in hypertensive patients (see Chapter 42). It must be borne in mind, however, that physiologic variability is such that some healthy women have high plasma uric acid levels without problems, so that uric acid values must be interpreted in the clinical context.

Glucose

Excretion of glucose increases soon after conception to approximately 10 times the nonpregnant value and remains high throughout pregnancy, although glycosuria is variable.⁸ The glycosuria is not related to changes in plasma glucose concentration and reflects decreased tubular reabsorption. In the nonpregnant individual, there is usually complete renal reabsorption of glucose, mostly in the proximal tubule, where there is a very high capacity for glucose transport. This maximum transport capacity

(T_{\max}) is not usually reached until plasma glucose increases to values in excess of ~200 mg/dl (11 mmol/l). The glycosuria of pregnancy is due to a decrease in T_{\max} or the inability of the renal tubules to cope with the increased filtered glucose load and does not reflect a metabolic disturbance.

Water-Soluble Vitamins and Amino Acids

Nicotinic acid, ascorbic acid, and folic acid are all excreted in increased amounts during pregnancy,⁷ which emphasizes the need for adequate vitamin supplementation.

Urinary excretion of most amino acids increases in pregnancy, probably as a result of decreased tubular reabsorption.³¹ There are distinct patterns. Glycine, histidine, threonine, serine, and alanine excretion increases early, and values remain elevated throughout pregnancy. Excretion of lysine, cystine, taurine, phenylalanine, valine, leucine, and tyrosine also increases in early pregnancy but later declines. Glutamic acid, methionine, and ornithine are excreted in slightly greater amounts than before pregnancy, isoleucine excretion is unchanged, and arginine excretion decreases, consistent with decreases in plasma arginine in normal pregnancy.

Acid-Base Balance

The generation of hydrogen ions increases in pregnancy because of an increased basal metabolism and greater food intake, but despite this, the blood concentration of hydrogen ions decreases; thus, plasma pH increases slightly (see Fig. 41.3). This mild alkalemia is respiratory in origin because pregnant women normally hyperventilate, leading to a primary decrease in arterial P_{CO_2} and secondary compensatory decreases in plasma bicarbonate concentration (see Fig. 41.3). A mild chronic respiratory alkalosis is a feature of normal pregnancy.

Potassium

Potassium excretion decreases, and there is a slow cumulative net potassium retention in pregnancy that is distributed between the enlarging maternal tissues and the developing fetus. The decrease in potassium excretion occurs in spite of the mild alkalosis and high aldosterone values of normal pregnancy and is at least partly due to the potent anti-mineralocorticoid action of progesterone (see later discussion).³²

Calcium

Calcium excretion increases two to three times during pregnancy because of the increased filtered load and despite some increase in tubular reabsorption. This could predispose to the formation of calcium stones, but increased magnesium and citrate, acidic glycoproteins, and nephrocalcin serve to inhibit calcium oxalate stone formation so that the incidence of stone formation is not increased in normal pregnancy.³³

Protein

Increased urinary total protein excretion in pregnancy should not be considered abnormal until it exceeds 500 mg in 24 hours,^{7,8,16,19} although many classifications and definitions of the hypertensive disorders of pregnancy still define more than 300 mg/24 h as abnormal.³⁴ There is usually a small increment in albumin excretion during the third trimester. Increased total protein and

albumin excretion may continue into the puerperium, with non-pregnant levels not restored until 5 to 6 months after delivery. The gestational changes may be related to alterations in glomerular permeability and charge selectivity as well as tubular function. In clinical practice, urine protein above 300 mg/24 h roughly correlates with 30 mg/dl in a random urine sample, but given the problems with dipstick tests, many still prefer a 24-hour or some timed quantitative determination. Use of a random urine protein-creatinine ratio is, however, a clinically useful alternative, with a threshold value of 30 mg/mmol creatinine (0.3 mg/mg) a reasonable cutoff for defining significant proteinuria.^{8,34,35}

Sodium

A massive, cumulative volume expansion occurs during pregnancy with an associated gradual retention of sodium of ~900 mmol, distributed between the products of conception and maternal extracellular space. This positive sodium balance develops despite a ~30% increase in filtered load and reflects an increase in tubular reabsorption that allows net additional sodium retention of ~2 to 3 mmol/day.³ Nevertheless, it is normal for sodium excretion to increase in pregnancy, reflecting the marked increase in sodium intake. Lithium clearance studies in women have indicated enhanced sodium reabsorption in the proximal tubule and distal nephron segments in late pregnancy, whereas animal studies have been contradictory.³⁶ The reason for the net renal sodium retention in pregnancy is not known. As shown in Figure 41.6, there are many factors operating both to increase and to decrease sodium excretion, and exactly how the normal balance of net retention is achieved remains a mystery. Several antinatriuretic systems are activated in normal pregnancy.³⁷ Renin, angiotensin, and aldosterone levels are all markedly increased, and the renin-angiotensin system (RAS) can be appropriately regulated around these new set points when changes occur in extracellular fluid volume. In addition to stimulating aldosterone release, physiologic levels of angiotensin II act directly on the proximal tubule to increase sodium reabsorption. However, a marked refractoriness develops to the vascular actions of angiotensin II in normal pregnancy,³⁷ which may blunt angiotensin II-dependent net sodium retention. The high aldo-

sterone levels of pregnancy will certainly promote renal sodium retention in the distal tubule and collecting duct. The very high levels of deoxycorticosterone (from 21-hydroxylation of progesterone) may also exert mineralocorticoid actions to promote sodium retention.³⁸ Estrogens increase markedly during human pregnancy and may directly induce renal sodium retention or act indirectly by enhancing the conversion of progesterone to deoxycorticosterone.³⁸ In addition to hormonal factors, the increased ureteral pressure and the decrease in systemic blood pressure both decrease sodium excretion.

The concentrations of several natriuretic agents also increase in pregnancy. Progesterone increases by 10 to 100 times, and these levels exert a marked anti-mineralocorticoid action by competing with aldosterone for the mineralocorticoid receptor.³⁸ Plasma atrial natriuretic peptide (ANP) levels are also moderately elevated,³⁹ as is nitric oxide.²⁰ In addition to natriuretic factors, the large increase in GFR leads to increased filtration of sodium (despite the small decrease in plasma sodium concentration), which will also increase sodium excretion. Decreases in plasma albumin concentration and the increment in effective renal plasma flow during pregnancy will also enhance sodium excretion by inhibiting sodium reabsorption.¹⁰ Animal studies have suggested that there is a generalized loss in pregnancy of natriuretic responsiveness to cGMP-dependent signals²⁰ due to increased inner medullary phosphodiesterase V activity.

Despite the many conflicting stimuli, net sodium retention and marked plasma volume expansion are normal in pregnancy. In the normal nonpregnant steady state, plasma volume expansion and renal sodium retention cannot coexist. However, pregnancy is not a steady state, and the volume sensing and regulatory systems are dramatically readjusted throughout pregnancy to accommodate and to maintain the volume expansion (see later discussion).

OSMOREGULATION

There is a very early decrease in plasma osmolality (P_{osm}) by ~10 mOsm/kg below the nonpregnant norm due to a reduction in plasma sodium and associated anions (see Fig. 41.3). Whereas a decrease in P_{osm} of this magnitude would completely suppress release of the antidiuretic hormone arginine vasopressin (AVP) in nonpregnant individuals, in pregnancy, the osmotic thresholds for AVP release as well as for thirst are reduced to recognize the reduced plasma osmolality as normal.⁴⁰ Figure 41.7 demonstrates the resetting of the relationship between plasma AVP and P_{osm} during normal pregnancy. The placental hormone human chorionic gonadotropin (which stimulates the release of ovarian relaxin)⁴¹ may have a role in this reduction in the osmotic threshold for AVP release.⁴⁰ Plasma volume status is a separate, non-osmotic determinant of AVP release, and this system is also reset to recognize the massively expanded plasma volume as normal. The metabolic clearance rate of AVP has increased four times by mid-pregnancy because of the release of cystine aminopeptidase (vasopressinase) from the placenta,⁴⁰ so the rate of AVP production must also be accelerated. Despite these marked alterations, the urinary concentrating and diluting capacity remain good, although there is a slight reduction in the maximum urine concentration in the second part of pregnancy.⁴⁰

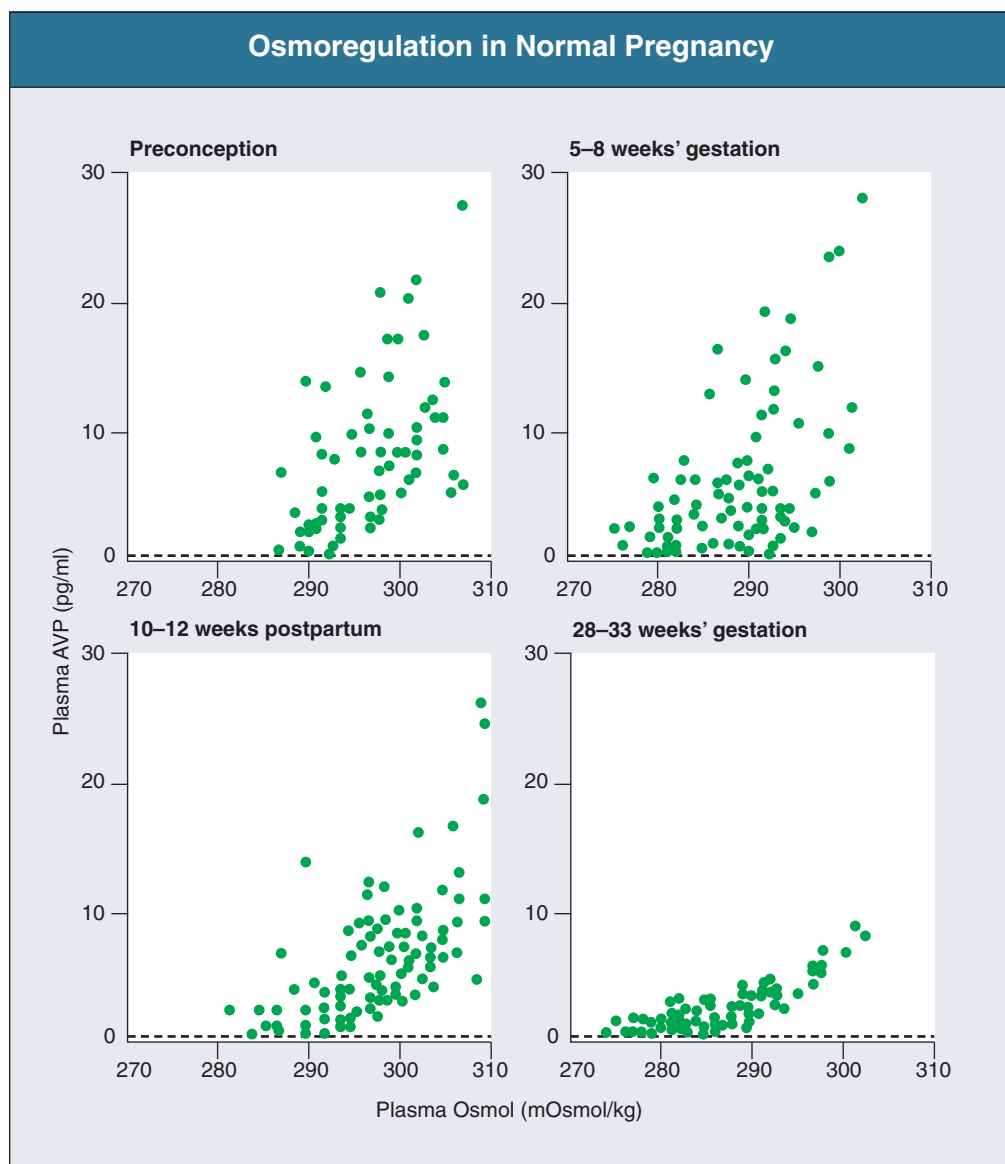

VOLUME REGULATION

As discussed previously, there is a continual sodium retention and cumulative volume expansion in pregnancy that reflects

Factors Influencing Sodium Excretion During Pregnancy	
Antinatriuretic	Natriuretic
Aldosterone	↑ Glomerular filtration rate
Angiotensin II	Progesterone
Estrogen	Atrial natriuretic peptide
Deoxycorticosterone	Nitric oxide
Supine posture	Prostaglandins
Upright posture	
Decreased blood pressure	
Increased ureteral pressure	
Placental shunting	

Figure 41.6 Factors influencing sodium excretion during pregnancy.

Figure 41.7 Osmoregulation in normal pregnancy. Relationship between plasma arginine vasopressin concentration (AVP) and plasma osmolarity (Osmol) during several 5% saline infusions in eight women before and during pregnancy. Each point represents an individual plasma measurement. There is a marked decrease in osmotic threshold for AVP release during pregnancy. Values for the osmotic threshold for thirst (not shown) were always 2 to 5 mOsmol/kg above AVP release thresholds and 10 mOsmol/kg lower in pregnancy.^{7,40}

complex readjustments of the various volume regulatory systems. These readjustments also permit volume expansion without increases in blood pressure; in fact, blood pressure decreases substantially as pregnancy proceeds (see Fig. 41.3). What happens to volume perception and regulatory systems in pregnancy can be considered in terms of the effective circulating volume.^{42,43} The RAS is an antinatriuretic system activated by volume depletion, and the increase in plasma renin activity and angiotensin and aldosterone concentrations of normal pregnancy suggests an underfill signal, despite the absolute increase in plasma volume. It has been suggested that the primary event in pregnancy is peripheral vasodilation that generates an underfill signal that leads to renal sodium retention.⁴² In contrast to the RAS, as discussed previously, both osmotic and nonosmotic control of AVP release is reset in a manner indicating that the expanded volume of pregnancy is sensed as normal.⁴⁰ The tubuloglomerular feedback system is suppressed by volume expansion in the nonpregnant state but is reset in pregnant rats to recognize the expanded volume and increased GFR as normal.¹⁴ Plasma ANP increases slightly in late pregnant women, but this is unlikely to

reflect a physiologic response to volume expansion because even greater increases in ANP are seen in volume-contracted, preeclamptic pregnancies.³⁹ Thus, volume regulation in pregnancy remains an enigma.

IMPACT OF MATERNAL HEMODYNAMIC CHANGES ON FETAL PROGRAMMING

There is strong evidence that women with normal pregnancies who have suboptimal increases in plasma volume are more likely to deliver babies small for gestational age. Fetal growth restriction is often seen in preeclamptic pregnancies in which volume contraction usually occurs.⁴⁴ Reductions in uterine blood flow (as occur in preeclampsia or when volume expansion is inadequate) and maternal (and thence fetal) malnutrition have been implicated in the pathogenesis of fetal growth restriction. There is considerable epidemiologic as well as animal evidence suggesting that adverse events *in utero* that lead to fetal growth restriction can program the offspring for the later development of hyperten-

sion, other cardiovascular events, and chronic kidney disease, at least in part due to reduction in nephron number.^{45,46} Thus, optimal maternal systemic and renal hemodynamic changes have a huge impact not only on fetal well-being but on the long-term health of the offspring.

Renal Complications in Normal Pregnancy

S. Ananth Karumanchi, Phyllis August, Tiina Podymow

This chapter discusses kidney disease that develops for the first time during pregnancy, particularly disorders specific to pregnancy, including preeclampsia, hypertensive disorders, and acute kidney injury. In addition, pregnant women are at risk for any of the renal diseases that occur in young women, which may develop coincidentally for the first time during pregnancy. Because many young women undergo urinalysis and blood pressure measurement for the first time during pregnancy, this means that previously undetected kidney disease may be identified. The management of pregnancy with preexisting kidney disease is discussed in Chapter 43. Urinary tract infection and stone disease present particular risks and management issues in pregnancy and are also discussed in Chapter 43.

URINALYSIS

For many young women, pregnancy is the first occasion that they have urinalysis and urine microscopy performed. Hematuria, proteinuria, and pyuria may be detected, either related to or coincidental to the pregnancy.

Hematuria

Microscopic hematuria can be detected at some time during pregnancy in about 20% of women, but it is persistent in only half of those and usually disappears after delivery, when it can be investigated further if it is still present. Persistent microscopic hematuria with normal blood pressure may be present in lupus nephritis, sickle cell trait, thin basement membrane nephropathy, IgA nephropathy, or polycystic kidneys and with renal calculi. The most common cause of gross hematuria in pregnancy is hemorrhagic bacterial cystitis; a less common cause is renal calculi, and rarely it may be bladder or renal neoplasms.

Proteinuria

The urinary excretion of protein rises during pregnancy because of an increase in glomerular filtration rate (GFR) (see Chapter 41), so that the 24-hour excretion of protein, normally below 150 mg/day, may reach 300 mg/day. The pregnancy-induced increase in GFR usually produces more substantial increases in protein excretion in patients with preexisting proteinuria. Patients with a history of glomerulonephritis in whom pre-pregnant levels of protein excretion are less than 1 g/24 h may excrete 2 to 6 g/24 h during a normal pregnancy because of glomerular hyperperfusion, without any other sign of exacerbation of the nephritis. In such women, plasma uric acid levels are unchanged if preeclampsia is not present.

The development of new and significant proteinuria during pregnancy is almost always associated with the development of preeclampsia and therefore needs thorough investigation, including the measurement of blood pressure, liver function tests, and determination of serum uric acid level. In the absence of urinary tract infection or preeclampsia, isolated proteinuria in pregnancy usually reflects new-onset glomerular disease, for example, primary glomerulonephritis such as IgA nephropathy or focal segmental glomerulosclerosis, or a systemic disease such as systemic lupus. If proteinuria is persistently detected by dipstick testing ($\geq 1+$ [100 mg/dl]), the urine protein-creatinine ratio in a random urine sample should be measured. A ratio above 0.3 (mg protein/mg creatinine) that corresponds to a protein excretion of more than 300 mg/24 h is needed to confirm proteinuria.

Pyuria

Isolated leukocyturia (pyuria) is common in normal pregnancy because of contamination by vaginal secretions. It requires no action other than ensuring that it disappears by 3 months postpartum.

RENAL BIOPSY

Percutaneous renal biopsy is usually avoided during pregnancy because of the fear of bleeding from the biopsy site, but it is not clear that the risk of hemorrhage is actually greater than in the nonpregnant state.¹ Renal biopsy is not usually required for the diagnosis and management of preeclampsia. Renal biopsy is indicated, however, if there is reason to suspect a renal disorder that may be treated successfully, especially in early pregnancy, while permitting the pregnancy to continue; this is discussed further in Chapter 43. Diseases in this category include lupus nephritis, minimal change nephrotic syndrome, immune-mediated interstitial nephritis, crescentic glomerulonephritis, and vasculitis. Percutaneous biopsy of the kidney may be performed with ultrasound localization in the usual prone position or with the woman lying on her right side.

KIDNEY SIZE AND HYDRONEPHROSIS

The volume, weight, and size of the kidneys increase in gestation; renal lengths increase by about 1 cm measured by ultrasound.² The collecting systems of both kidneys are normally dilated during pregnancy (see Chapter 41, Fig. 41.1), most marked on the right. The dilation is probably caused by hormonal changes of pregnancy and also by ureteral obstruction by

the pregnant uterus. Because ureteral dilation is so common during normal gestation, it may be difficult to diagnose frank urinary obstruction. An unusual syndrome of late pregnancy is characterized by abdominal pain, marked hydronephrosis, and a variable increase in serum creatinine, managed successfully by the placement of ureteral stents.² Because “physiologic hydronephrosis” is so common, pregnant women are particularly susceptible to ascending pyelonephritis as a result of bladder infections. In the immediate puerperium, a rare occurrence is massive hematuria, usually from the right ureter, which subsides spontaneously and has been attributed to decompression of the partially obstructed right collecting system.

URINARY INFECTION AND ASYMPTOMATIC BACTERIURIA

Urinary frequency, sometimes accompanied by dysuria, is common during the latter half of pregnancy, even when the urine is not infected, because of pressure on the bladder from an enlarged pregnant uterus.

Urinary Tract Infection

Urinary tract infections that may present as cystitis or acute pyelonephritis complicates 1% to 2% of pregnancies. Urinary stasis and anatomic displacement of the ureters during pregnancy contribute to pathogenesis. In pregnancy, quantitative urine cultures should be obtained in women with persistent leukocyturia (more than two or three white blood cells per high-power field in spun sediment) or symptoms of cystitis. If there are more than 10^5 bacteria of a single species per milliliter of urine, significant bacteriuria is present. Acute pyelonephritis or cystitis can be diagnosed even with 10^2 bacteria/ml if it is accompanied by clinical symptoms. Acute pyelonephritis is a serious complication during pregnancy and usually presents between 20 and 28 weeks of gestation with fevers, loin pain, and dysuria. Bacteremia, usually accompanying pyelonephritis, can progress to endotoxic shock, disseminated intravascular coagulation, and acute renal failure. Pregnant women with acute pyelonephritis should be admitted to the hospital and treated with intravenous antibiotics and hydration. The intravenous administration of cephalosporins or gentamicin for 24 to 48 hours or until the patient is afebrile is followed by oral antibiotics for 10 to 14 days. Antibiotic regimens for treatment of urinary tract infection in pregnancy are shown in Figure 43.6.

Asymptomatic Bacteriuria

Asymptomatic bacteriuria complicates 2% to 10% of pregnancies and may occur without pyuria. It is frequently associated with a reduction in the concentrating ability of the kidney. The organisms associated with asymptomatic bacteriuria are shown in Figure 42.1. Reagent strip testing for asymptomatic bacteriuria is associated with a high false-negative rate, and quantitative urine culture should be performed to rule out significant bacteriuria.

Asymptomatic bacteriuria has been associated with an increased risk of premature delivery and low birth weight. Treatment of asymptomatic bacteriuria during pregnancy reduces these complications and improves perinatal morbidity and mortality.³ Without treatment, asymptomatic bacteriuria will persist in more than 80% of women and may progress to symptomatic urinary tract infection or acute pyelonephritis. Screening for

Organisms Most Commonly Responsible for Asymptomatic Bacteriuria in Pregnancy

<i>Escherichia coli</i> (>70% of infections)
<i>Klebsiella</i> species
<i>Proteus</i> species (particularly in diabetic women or urinary tract obstruction)
Enterococci
Staphylococci, especially <i>Staphylococcus saprophyticus</i>
<i>Pseudomonas</i>
Streptococci

Figure 42.1 Organisms most commonly responsible for asymptomatic bacteriuria in pregnancy.

Safety of Antibiotics Commonly Used to Treat Urine Infection in Pregnancy

Category of Drug	Antibiotic
A. Drugs taken by large numbers of pregnant women without any proven fetal harm	Amoxicillin, ampicillin Cefalexin, cephalothin Nalidixic acid Nitrofurantoin Penicillins
B1. Drugs taken by a limited number of pregnant women without proven fetal harm; animal studies show no increase in fetal damage	Aztreonam Ceftazidime, cefotaxime, cefaclor Amoxicillin/clavulanic acid Flxacillin (flucloxacillin) Piperacillin
B2. As B1, but animal data are unavailable	Vancomycin
B3. As B1, but animal studies show an increase in fetal damage	Ciprofloxacin, norfloxacin, ofloxacin Imipenem, trimethoprim
C. Drugs whose pharmacologic effects are suspected of causing fetal harm	Sulfonamides Cotrimoxazole Fusidic acid
D. Drugs that are proven to cause fetal harm	Tetracyclines Gentamicin and other aminoglycosides Chloramphenicol

Figure 42.2 Safety of antibiotics commonly used to treat urinary tract infection in pregnancy.

asymptomatic bacteriuria with a urine culture is recommended during the first prenatal visit and is repeated only in high-risk women, such as those with a history of recurrent urinary infections or urinary tract anomalies. If asymptomatic bacteriuria is found, prompt treatment is warranted, usually with a cephalosporin, for 3 days; a single dose of fosfomycin can also be used (see Fig. 43.6). Antibiotics useful in treating urinary infections during pregnancy are listed in Figure 42.2. Trimethoprim-sulfamethoxazole (cotrimoxazole) is contraindicated in early pregnancy because of its association with birth defects. Tetracycline and chloramphenicol are also contraindicated. Use of quinolones is discouraged during pregnancy because of some evidence of teratogenicity in animals. Women treated for asymptomatic bacteriuria should have a repeated urine culture 2 weeks after therapy to ensure that bacteriuria has been eradicated. Suppressive therapy with nitrofurantoin or cephalexin is recommended for those patients with bacteriuria that persists after two courses of therapy. Prolonged suppressive treatment of bacteriuria reduces the incidence of pyelonephritis.⁴

Classification System for Hypertension in Pregnancy

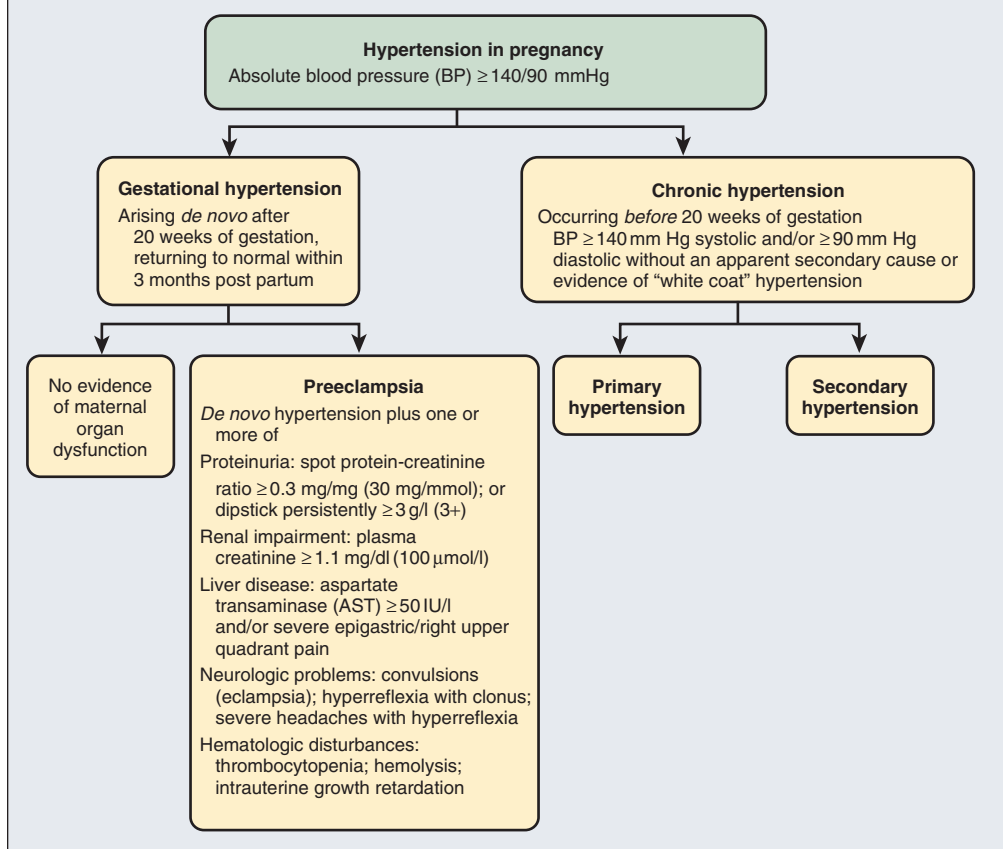

Figure 42.3 Classification of hypertension in pregnancy.

RENAL CALCULI

Although intestinal absorption and urinary excretion of calcium are increased during pregnancy, there is no evidence that the risk of nephrolithiasis is increased. Women who have had kidney stones can be reassured that pregnancy is not likely to increase stone formation. The management of symptomatic stone disease in pregnancy is discussed further in Chapter 43.

HYPERTENSIVE DISORDERS OF PREGNANCY

Hypertensive disorders of pregnancy can be considered in three categories:

1. gestational hypertension, including preeclampsia and eclampsia;
2. chronic or preexisting hypertension of any cause; and
3. preeclampsia superimposed on chronic hypertension.

Figure 42.3 illustrates the various hypertensive disorders of pregnancy and the criteria used to make the distinction. Preeclampsia (pure or superimposed, categories 1 and 3) poses the greatest threat to fetal survival and is the disorder most often associated with severe maternal complications (including fatalities) (Fig. 42.4). The majority of women in the second category have primary hypertension, and their pregnancies usually remain uncomplicated and end successfully. On occasion, however, the high blood pressure is due to specific causes, including pheochromocytoma, Cushing's syndrome, renal artery stenosis,

Widespread Clinical Implications of Preeclampsia

Figure 42.4 Widespread clinical implications of preeclampsia. DIC, disseminated intravascular coagulation.

and primary renal disease,^{5,6} and some of these women with secondary forms of hypertension do poorly during gestation. Thus, pheochromocytoma, although rare, may present for the first time during gestation and is especially lethal when it is unsuspected; whereas when it is diagnosed, it can be managed to a successful outcome, either surgically or pharmacologically (with α -blockade), depending on the stage of pregnancy.⁵ Cushing's syndrome has been associated with exacerbations of hypertension during pregnancy and poor fetal outcomes. Finally, both angioplasty and stent placement have been successfully performed in pregnant women with renal artery stenosis.⁵

GESTATIONAL HYPERTENSION

Pregnant women with blood pressure above 140/90 mm Hg, without proteinuria, and whose blood pressure was lower before pregnancy are described as having gestational hypertension. There are a range of possible causes. Some women, usually with a strong family history of primary hypertension, have a normal blood pressure throughout most of pregnancy, but at the end of the third trimester, blood pressure tends to rise to approach the higher pre-pregnant level. Usually there is no protein in the urine, and the serum uric acid is not elevated. There is evidence that transient hypertension of pregnancy occurs in women destined to have primary hypertension later in life (analogous to women with gestational hyperglycemia who eventually develop type 2 diabetes).

A substantial proportion of women (approximately 30%) with gestational hypertension have an early phase of preeclampsia, in which proteinuria has not yet appeared. This subgroup of patients may have some evidence of glomerular endotheliosis on renal biopsy (Fig. 42.5).⁷ On occasion, the elevated blood pressure has a psychiatric cause, such as an anxiety or panic disorder. A rare group of patients have activating mineralocorticoid receptor mutations that result in an exaggerated sensitivity to the usually weak mineralocorticoid effect of progesterone.⁸ They manifest salt-sensitive hypertension, accompanied by hypokalemia, but virtually undetectable aldosterone levels, most marked during pregnancy as progesterone levels rise. The administration of large amounts of intravenous saline during a cesarean section can sometimes result in postpartum hypertension and edema that disappear in a few days when the large salt load is excreted.

PREECLAMPSIA

Definition

Preeclampsia is the most frequently encountered renal complication of pregnancy. It is characterized by the new onset of hypertension and proteinuria, usually after 20 weeks of pregnancy, and is commonly associated with edema and hyperuricemia. Blood pressure of 140/90 mm Hg or higher during pregnancy is required for the diagnosis.⁹ It was previously recommended that a rise in systolic blood pressure of more than 30 mm Hg or in diastolic blood pressure of more than 15 mm Hg from baseline values was sufficient to define hypertension; however, epidemiologic data indicate that outcomes are similar whatever the magnitude of the rise, provided blood pressure remains below 140/90 mm Hg. Nevertheless, the U.S. National High Blood Pressure Education Program still recommends that women with blood pressure below 140/90 mm Hg who have experienced an increase of 30 or 15 mm Hg in systolic or diastolic levels, respectively, should be managed as high-risk patients. Proteinuria is

Figure 42.5 Glomerular endotheliosis. **A**, Normal glomerulus. (Light microscopy, periodic acid-Schiff stain; magnification $\times 40$.) **B**, Glomerulus from a patient with preeclampsia. Note glomerular basement membrane (arrows) and marked reduction of capillary lumen (CL) due to swollen endothelial cell cytoplasm. (Original magnification $\times 7500$.) (Courtesy Prof. P. Furness, University of Leicester, UK)

Criteria for the Diagnosis of Severe Preeclampsia
In patients with preeclampsia, severe preeclampsia can be diagnosed if any one of the following criteria is present:
Blood pressure 160 mm Hg systolic or 110 mmHg diastolic or higher on two separate occasions at least 6 hours apart
Proteinuria Random urine protein-creatinine ratio ≥ 5 mg/mg (500mg/mmol) or proteinuria > 5 g/24 h
Oliguria < 500 ml in 24 hours
Cerebral or visual disturbances such as cerebrovascular accident, seizures, or visual loss
Pulmonary edema
Epigastric or right upper quadrant pain
Hepatocellular injury (serum transaminases at least twice normal)
Serum lactate dehydrogenase: > 600 IU/l
Thrombocytopenia $< 100 \times 10^9/l$
Fetal growth restriction (birth weight less than 10th percentile for the gestational age)

Figure 42.6 Criteria for the diagnosis of severe preeclampsia. (Modified from reference 9.)

defined as urine protein-creatinine ratio above 0.3 mg/mg (30 mg/mmol), which is sufficiently reliable to avoid the need for 24-hour urine collection. Finally, although serum uric acid is not included in the formal definition of preeclampsia, uric acid level above 5.5 mg/dl (325 μ mol/l) may point to a diagnosis of preeclampsia, especially in patients with preexisting renal disease or hypertension although other causes of hyperuricemia should always be considered (see Chapter 43). Preeclampsia is considered severe with urine protein-creatinine ratio above 5, with blood pressure of 160/110 mm Hg or higher, with evidence of the HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count) or central nervous system dysfunction, or with the presence of intrauterine fetal growth restriction (Fig. 42.6).

Epidemiology

Preeclampsia complicates approximately 5% of all pregnancies. It is about twice as common in first pregnancies as in multigravidas. Preeclampsia is also slightly more common in multigravidas who have a new partner, suggesting that prior exposure to paternal antigens may be protective.¹⁰ However, recent evidence from a large Norwegian birth registry suggests that prolonged interpregnancy interval, rather than primipaternity, may account for this increase in risk, for reasons that are unclear. Other predisposing factors include preexisting hypertension, chronic renal disease, obesity, diabetes mellitus, thrombophilias (factor V Leiden, antiphospholipid syndrome, and antithrombin III deficiency), and multiple gestation (Fig. 42.7). It occurs more frequently in women whose mothers had preeclampsia and in women whose fathers were products of a preeclamptic pregnancy, perhaps because the placenta itself is a creation of both the mother and the father.¹⁰ The incidence of preeclampsia is also higher in women who live in high altitudes, suggesting that hypoxia may contribute to the development of the syndrome.

Pathogenesis

Preeclampsia occurs only in the presence of the placenta, even when there is no fetus (as in hydatidiform mole) and usually

Risk Factors for the Development of Preeclampsia
Preeclampsia in prior pregnancy
Family history of preeclampsia
Nulliparity
Multiple gestation
Molar pregnancies
Older maternal age
Obesity
Preexisting hypertension
Preexisting chronic kidney disease
Diabetes mellitus
Thrombotic vascular disease (antithrombin III deficiency, protein C or S deficiency, factor V Leiden, antiphospholipid antibody syndrome)
Trisomy 13 fetus
Fetal hydrops
High altitude

Figure 42.7 Risk factors for the development of preeclampsia.

remits when the placenta is delivered. The placenta in preeclampsia is often abnormal, with evidence of hypoperfusion and ischemia. Preeclampsia is characterized by widespread systemic vascular endothelial dysfunction and microangiopathy in the mother but not in the fetus. It is currently thought that preeclampsia is due to a circulating factor or factors produced by the diseased placenta that induce maternal vascular endothelial dysfunction.¹¹

Abnormal Placentation in Preeclampsia

The characteristic placental lesion in preeclampsia is a diminution in endovascular invasion by cytotrophoblasts and a decrease in remodeling of the uterine spiral arterioles.¹² The hypothesis that defective trophoblastic invasion with accompanying uteroplacental hypoperfusion may lead to preeclampsia is supported by animal and human studies. Placentas from pregnancies with advanced preeclampsia often have numerous placental infarcts and sclerotic narrowing of arterioles.¹⁰ Uteroplacental blood flow is usually diminished and uterine vascular resistance increased in preeclamptic women. Placental ischemia induced by mechanical constriction of the uterine arteries or aorta produces hypertension, proteinuria, and, variably, glomerular endotheliosis in several animal species.¹³ However, placental ischemia alone, as seen in many cases of intrauterine growth restriction, does not appear to be sufficient to produce preeclampsia.

The Preeclampsia Factors

There has been an intense search for circulating factors that may cause the maternal syndrome of preeclampsia. Increased sensitivity to the vasopressor effects of angiotensin is a feature of preeclampsia, perhaps due to increased plasma concentrations of angiotensin AT₁-bradykinin B₂ receptor heterodimers.¹⁰ Circulating concentrations of agonistic antibodies to the angiotensin AT₁ receptor have been reported in women with preeclampsia¹⁴ and are also encountered in other examples of vascular injury, such as vascular rejection, suggesting that they may be secondary to the generalized microangiopathy of preeclampsia. Reactive free oxygen radicals may have a causal role in preeclampsia.¹¹ In some but not all studies, markers of oxidative stress are elevated

in women with preeclampsia. Decreased intake of the antioxidant vitamin C and low circulating ascorbic acid levels are associated with an increased risk of preeclampsia. However, a randomized therapeutic trial of antioxidants (vitamins C and E) in pregnant women did not prevent preeclampsia, suggesting that oxidant stress is unlikely to be the primary mediator.¹⁵

“Export” of fragments of trophoblastic material from the diseased placenta into the circulation has also been suggested as a possible cause for the generalized microangiopathy of preeclampsia.¹¹

Circulating Antiangiogenic Factors

sFlt-1 (soluble fms-like tyrosine kinase 1, also referred to as sVEGFR-1) production is increased in the placenta in preeclamptic women.¹⁶ sFlt-1 is a secreted protein, a splice variant of the vascular endothelial growth factor (VEGF) receptor Flt-1 lacking the transmembrane cytoplasmic domain of the membrane-bound receptor. It is a potent circulating antagonist to VEGF and placental growth factor (PlGF) (Fig. 42.8). Both VEGF and PlGF are made by the placenta and circulate in high concentration during pregnancy. VEGF is also synthesized by glomerular podocytes and vascular endothelial cells. Circulating sFlt-1 levels are greatly increased in women with established preeclampsia and before onset of clinical symptoms, whereas free PlGF levels are decreased.¹⁷ When it is administered to pregnant and non-pregnant rats, sFlt-1 produces hypertension, proteinuria, and glomerular endotheliosis resembling the human syndrome of preeclampsia. The glomerular lesion in these experimental animals, consisting of severe glomerular endothelial swelling and loss of endothelial fenestrae with relatively preserved foot processes in association with heavy proteinuria, is striking in its resemblance to human preeclampsia (see Fig. 42.5).^{16,18}

The concentration of circulating sFlt-1 starts to rise near the end of the second trimester in women destined to have

preeclampsia, 4 to 5 weeks before clinical manifestations such as hypertension and proteinuria are first detected.¹⁷ By the time clinically overt preeclampsia has developed, plasma sFlt-1 is two to four times higher than in normal pregnancy at the same stage of gestation. The concentration of sFlt-1 in plasma is higher in patients with severe preeclampsia than in those with milder disease.¹⁹ There is also a modest but significant decrease in circulating free PlGF levels in the first trimester in women who later develop preeclampsia, but from mid-pregnancy on, the concentration of PlGF in plasma falls at the time when sFlt-1 levels are rising.¹⁹ Because unbound PlGF is freely filtered, urinary PlGF levels may prove to be a predictor of subsequent preeclampsia.¹⁹ Women carrying trisomy 13 fetuses have an increased risk of preeclampsia and high circulating concentrations of sFlt-1, perhaps not surprising because the gene for Flt-1/sFlt-1 is located on chromosome 13.²⁰

The possibility that an antagonist of VEGF and PlGF might play a role in preeclampsia has a sound physiologic basis. As well as being potent promoters of angiogenesis, VEGF and PlGF are known to induce the synthesis of nitric oxide and vasodilating prostacyclins in endothelial cells, decreasing vascular tone and blood pressure. VEGF, synthesized in large amounts by glomerular podocytes, may be important in maintaining the health and healing of glomerular vascular endothelial cells, so that its absence induces proteinuria and glomerular endotheliosis.²¹ The organs targeted in preeclampsia, such as the glomerulus and the hepatic sinusoids, have fenestrated endothelia. VEGF induces endothelial fenestrae *in vitro*, and even a 50% decrease in VEGF production in the glomerulus in mice leads to glomerular endotheliosis and loss of glomerular endothelial fenestrae.²¹ Antagonists of VEGF, used in cancer therapy, sometimes produce hypertension, proteinuria, and reversible posterior leukoencephalopathy—hallmarks of preeclampsia and eclampsia.¹⁰ Furthermore, exogenous VEGF and PlGF can reverse the

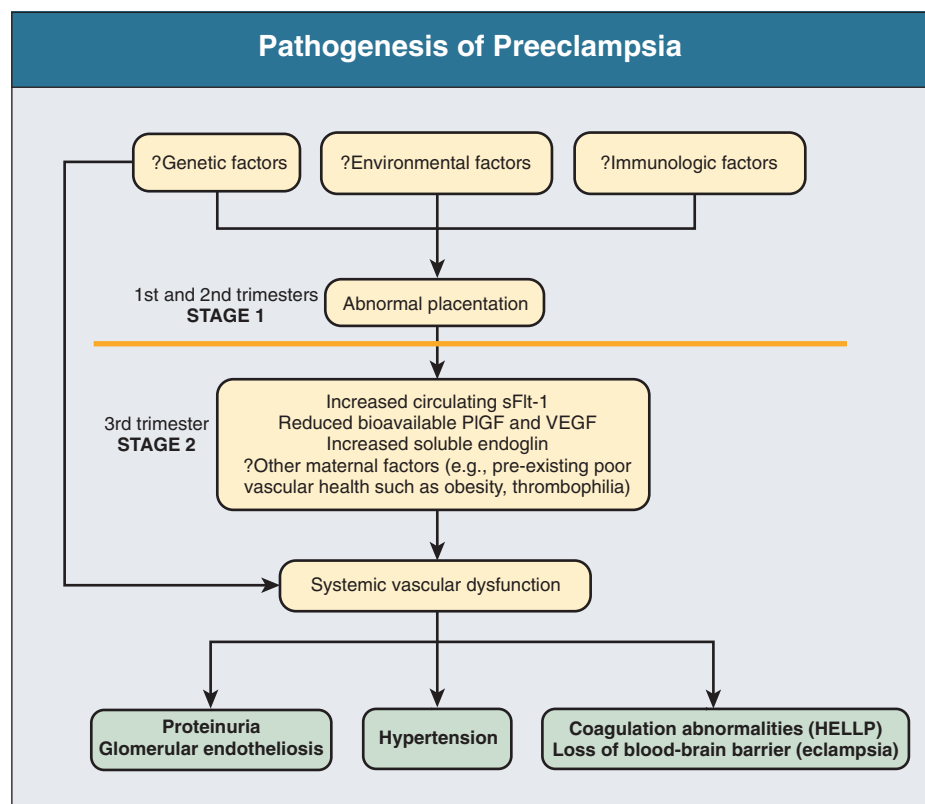

Figure 42.8 sFlt-1 and sEng cause endothelial dysfunction by antagonizing VEGF and TGF-β1 signaling. There is mounting evidence that vascular endothelial growth factor (VEGF) and transforming growth factor β1 (TGF-β1) are required to maintain endothelial health in several tissues, including the kidney and perhaps the placenta. During normal pregnancy, vascular homeostasis is maintained by physiologic levels of VEGF and TGF-β1 signaling in the vasculature. In preeclampsia, excess placental secretion of sFlt-1 and sEng (two endogenous circulating antiangiogenic proteins) inhibits VEGF and TGF-β1 signaling, respectively, in the vasculature. This results in endothelial cell dysfunction, including decreased prostacyclin, nitric oxide production, and release of procoagulant proteins. PlGF, placental growth factor. antiangiogenic effects of preeclamptic blood *in vitro*.¹⁶ Thus, the antiangiogenic effects of sFlt-1 may account for many of the manifestations of preeclampsia, including the unique glomerular changes.

The likely role of sFlt-1 in the pathogenesis of preeclampsia is summarized in Figure 42.9. Overproduction of sFlt-1 could explain susceptibility to preeclampsia in multiple gestation, hydatidiform mole, trisomy 13, and possibly first pregnancy. Alternatively, preeclampsia could follow sensitization of the maternal vascular endothelium to the antiangiogenic effects of sFlt-1. Such sensitization might occur in obesity, preexisting hypertension or renal disease, and diabetes. The average sFlt-1 level in the serum of obese patients with preeclampsia is lower than that in thinner preeclamptic patients.¹⁷ Hypoxia is known to increase the production of sFlt-1 by placental trophoblasts,¹⁰ so that placental ischemia might trigger preeclampsia. Placental ischemia is common but not universal in preeclampsia. Placental infarction unaccompanied by preeclampsia is a common finding in mothers with sickle cell anemia and with intrauterine growth restriction. Placental overproduction of sFlt-1, whatever its cause, might itself decrease angiogenesis locally and result in placental ischemia, thereby initiating a vicious circle leading to even more sFlt-1 production.

These three factors may all contribute in variable degree to the pathogenesis of preeclampsia: (1) a change in the balance of circulating factors controlling angiogenesis-antiangiogenesis, attributable to placental overproduction of sFlt-1 and underproduction of PlGF; (2) increased vascular endothelial sensitivity to such factors²²; and (3) placental ischemia. It is not surprising that in human pregnancy, characterized initially by rapid angiogenesis localized to the placenta, followed as pregnancy terminates by regression of blood vessel growth, there should

sometimes occur systemic manifestations of a derangement of this process.

Another antiangiogenic protein, soluble endoglin (sEng), is also upregulated in preeclampsia in a pattern similar to that of sFlt-1. sEng is a truncated form of endoglin (CD105), a cell surface receptor for transforming growth factor β 1 (TGF- β 1) (see Fig. 42.8). Soluble endoglin amplifies the vascular damage mediated by sFlt-1 in pregnant rats, inducing a severe preeclampsia-like syndrome with features of the HELLP syndrome.²³ This effect may be mediated by interference with nitric oxide-mediated vasodilation. As with sFlt-1, circulating sEng levels are elevated weeks before preeclampsia onset.²⁴ The precise role of soluble endoglin in preeclampsia and its relationship with sFlt-1 are currently being explored.

Pathology

Preeclampsia is associated with a unique and specific glomerular appearance referred to as glomerular endotheliosis (see Fig. 42.5). By light microscopy, the glomerular capillary lumina are narrowed and appear bloodless, and the glomeruli are enlarged. Unlike other thrombotic microangiopathies, the endotheliosis of preeclampsia is usually not accompanied by prominent capillary thrombi. Immunofluorescence may reveal deposition of fibrinogen derivatives, especially when signs of systemic thrombotic microangiopathy are prominent. There are no immune deposits in the glomeruli, and serum complement levels are normal. Electron microscopy shows relative preservation of the podocyte foot processes despite heavy proteinuria, but there is loss of endothelial fenestrae, and endothelial cells become swollen and separated from the basement membrane by electron-lucent material.¹⁸ Mild glomerular endotheliosis has been noted in up to 30% of

patients with pregnancy-induced hypertension without proteinuria,^{7,25} suggesting that some cases of pregnancy-induced hypertension may reflect an earlier or milder form of preeclampsia. The glomerular changes usually disappear within 8 weeks of delivery, coinciding with resolution of the hypertension and proteinuria. Focal segmental glomerulosclerosis is said to accompany the generalized glomerular endotheliosis of preeclampsia in up to 50% of cases.¹⁰ Although this change has been taken by some to suggest that there was kidney disease before pregnancy, it seems possible that it is the consequence of the preeclamptic process itself because similar changes may develop rapidly when glomerular endotheliosis is induced in animals.²¹

Clinical Manifestations

Preeclampsia is the most frequently encountered renal complication of pregnancy. It is characterized by the new onset of hypertension and proteinuria, usually during the last trimester of pregnancy, and is commonly associated with edema and hyperuricemia. Preeclampsia is characterized by widespread vascular endothelial dysfunction and microangiopathy in the mother but not in the fetus. The predominant target organ may be the brain (seizures or eclampsia), the liver (HELLP syndrome), or the kidney (glomerular endotheliosis and proteinuria) (see Fig. 42.4). Severe preeclampsia is also associated with intrauterine growth restriction and small for gestational age babies.

Hypertension

During normal pregnancy, peripheral vascular resistance and systemic arterial blood pressure are decreased; but in preeclampsia, these changes are reversed. Increased peripheral vascular resistance rather than increased cardiac output is the chief cause of hypertension.¹⁰ As in other forms of hypertension, sympathetic activation is prominent, and there is an exaggerated response to infusions of angiotensin II and other hypertensive stimuli.¹⁰

In preeclampsia, the renin-angiotensin-aldosterone system (RAS) is suppressed,²⁶ suggesting that vasoconstriction, increased peripheral vascular resistance, and renal sodium and water retention are initial events, resulting in an increased effective circulating blood volume and subsequent RAS suppression. This is consistent with the observation that although total plasma volume is slightly decreased, the hypertension of preeclampsia is exacerbated by salt loading and at least partly ameliorated by diuretics and salt deprivation.¹⁰ A comparable decrease in total plasma volume with an increase in peripheral vascular resistance and arterial blood pressure can be produced by the infusion into normal subjects of norepinephrine and other vasoconstrictors. The vasoconstriction of preeclampsia appears to be mediated by alterations in several vasoactive molecules, including the vasoconstrictors norepinephrine, endothelin, and perhaps thromboxane and the vasodilators prostacyclin and perhaps nitric oxide.

Edema

Sudden weight gain, with edema of the feet, hands, and face, is a common presenting symptom in preeclampsia. Women with preeclampsia excrete a much smaller percentage of an intravenous saline load than do normal pregnant women.¹⁰ Because there is RAS suppression, this implies primary renal retention of salt and water. The edema of preeclampsia thus resembles the “overflow” edema of acute glomerulonephritis or of acute ischemic renal failure with volume overload.

Figure 42.10 Renal abnormalities in preeclampsia. GFR, glomerular filtration rate.

A generalized increase in capillary permeability is unlikely to explain preeclamptic edema because the concentration of protein in interstitial fluid from preeclamptic patients is not elevated.¹⁰ Hypoalbuminemia is common, and it may contribute to edema formation in some patients.

Renal Function, Proteinuria, and the Urinary Sediment

Abnormalities of renal function in preeclampsia are summarized in Figure 42.10. GFR and renal plasma flow are uniformly decreased, compared with the increases in normal pregnancy. Blood urea nitrogen and serum creatinine concentrations often remain in the nonpregnant normal range, despite a significant decrease in GFR from the elevated levels of normal pregnancy. Simultaneous measurements of GFR and renal plasma flow indicate that the filtration fraction is lower during preeclampsia than in normal women during the last trimester of pregnancy.^{18,27}

The urinary sediment is usually “bland” in preeclampsia, with few leukocytes, erythrocytes, or cellular casts. Hyaline casts may be present when proteinuria is heavy. The presence of many erythrocytes or erythrocyte casts suggests glomerulonephritis. The proteinuria of preeclampsia is “nonselective,” that is, whereas most of the urinary protein is albumin, high-molecular-weight proteins are present as well.²⁷ After delivery, proteinuria usually disappears within 7 to 10 days; in a few women, it may persist, although gradually diminishing, for 3 to 6 months.

Uric Acid

A disproportionate fall in uric acid clearance is a key feature of preeclampsia. The serum uric acid concentration rises as preeclampsia progresses; a level above 5.5 mg/dl (325 μ mol/l) is a strong indicator of preeclampsia, and a level above 7.8 mg/dl (460 μ mol/l) is associated with significant maternal morbidity. The degree of uric acid elevation correlates with the severity of proteinuria and renal pathologic changes and with fetal demise.¹⁰ Often, the elevation of uric acid precedes the onset of proteinuria and changes in GFR. Lowering of serum uric acid by the administration of probenecid does not alter the hypertension and proteinuria of preeclampsia, so it is likely that hyperuricemia is a secondary rather than a primary phenomenon, analogous to the disproportionate fall in urate clearance produced in normal human subjects by vasoconstrictors like angiotensin II and

norepinephrine.¹⁰ Nevertheless, rodent studies suggest that hyperuricemia may play a pathogenic role by contributing to the vascular damage and hypertension.²⁸

Neurologic Abnormalities

The sudden development of seizures (eclampsia), together with headache, blurred vision, or temporary loss of vision, has been attributed to brain edema, thrombotic microangiopathy, and cerebral vasoconstriction. Sudden, marked elevations of blood pressure usually contribute to the severe cerebral edema that is a hallmark at postmortem examination of women who die of eclampsia. Hyperactive tendon reflexes often precede convulsions. The cerebral edema of eclampsia involves predominantly the posterior portions of the white matter; it is referred to as reversible posterior leukoencephalopathy syndrome and is best visualized by magnetic resonance imaging.²⁹ Treatment with intravenous magnesium sulfate usually lowers blood pressure and reduces central nervous system irritability, but it does not improve renal function. On occasion, seizures occur postpartum, usually within 4 days but very rarely as long as 3 to 4 weeks after delivery in women in whom preeclampsia, although probably present, was not detected during the pregnancy.

HELLP Syndrome

This term is applied to patients with preeclampsia in whom the clinical picture is dominated by hemolysis, elevated liver enzymes, and low platelet count, all occurring as a result of the generalized maternal vascular dysfunction of preeclampsia.³⁰ Very occasionally, subcapsular liver hemorrhage or liver rupture may develop. HELLP syndrome occurs in 10% to 20% of patients with preeclampsia and is one of its most severe forms. Symptoms and signs usually disappear promptly after delivery, although laboratory measures may transiently worsen in the first 24 hours but improve within 7 days after delivery. Thrombocytopenia is a consequence of consumption coagulopathy. It does not respond to exchange transfusion but usually disappears by 1 week postpartum.

Natural History

After delivery, the hypertension and proteinuria of preeclampsia usually disappear within a few days to weeks, but complete resolution may occasionally take longer. In exceptional cases, proteinuria lingers up to 6 months after delivery. Renal biopsy is indicated if proteinuria persists more than 6 months or earlier if the proteinuria is accompanied by an active urine sediment or rapidly deteriorating renal function.

Considerable evidence suggests that preeclampsia predisposes women to late vascular disease.^{31,32} Fifteen years after an episode of preeclampsia, the incidence of hypertension is five times that found in women with normal pregnancies who never had preeclampsia (37% versus 7%).³³ This tendency to later hypertension appears to be the result of preeclampsia rather than inherited factors because the same risk is not found in the siblings of preeclamptic patients.³³ Epidemiologic studies suggest that preeclampsia predicts remote cardiovascular deaths.³⁴ Preeclampsia is also a marker for increased risk of subsequent end-stage renal disease, although the absolute risk is low.³⁵

Prevention

Because preeclampsia occurs more frequently in women with chronic hypertension, it is thought that if high blood pressure is

Management of Preeclampsia	
Clinical Problem	Management
Assess indications for delivery	Always review whether an indication for delivery is present by clinical and laboratory monitoring
Control blood pressure (BP)	Acute treatment if BP \geq 170/110 mmHg Chronic treatment if BP \geq 140/90 mmHg
Eclampsia prophylaxis or treatment	Diazepam 10–20 mg IV to terminate convulsions Magnesium sulfate for persistent neurologic signs (also an indication for delivery): 4 g IV over 20 min, then 1.5 g/h for 48 h
Supportive therapies (sometimes required)	Platelet infusion if count $<$ 20–40 $\times 10^9$ /l Fresh-frozen plasma for microangiopathy or for reduced clotting factors Dialysis for established acute kidney injury
Progressive decline in renal, hepatic, or clotting function or of fetal growth	Delivery

Figure 42.11 Management of preeclampsia.

controlled in such women, the risk of preeclampsia is lowered, but this is not yet known with certainty. Low-dose aspirin (75–150 mg daily) is said to reduce the incidence of preeclampsia, but this has not been demonstrated in large prospective studies.³⁶ A meta-analysis suggested that antiplatelet agents have a modest benefit, with a relative risk of preeclampsia of 0.81 for aspirin-treated patients.³⁷ Because the benefits of aspirin prophylaxis are modest, it should be used only in high-risk women, such as those with underlying renal disease or preexisting hypertension. Oral calcium supplements may reduce the likelihood of preeclampsia in women whose calcium intake is extremely low.³⁸ Vitamin C and vitamin E do not protect against preeclampsia.¹⁵

Treatment

Figure 42.11 lists the key management options for patients with preeclampsia. The most reliable treatment of preeclampsia is delivery. Removal of the placenta usually produces prompt improvement, although in a few cases in which the disease has been explosive, symptoms may progress for several days, even after delivery. Unexpected uterine hemorrhage may produce shock and cortical necrosis, and excessive saline infusions given to prevent that eventuality may trigger pulmonary edema or exacerbate hypertension.

The hypertension of preeclampsia usually responds to pharmacologic treatment. Prompt lowering of the blood pressure is important to reduce the risk of cerebral edema, cerebral hemorrhage, and eclampsia. Blood pressure should be maintained below 140/90 mm Hg; however, it is important to not lower the blood pressure below 120/80 mm Hg as relative hypotension may further compromise the fetoplacental blood flow.³⁹ Figure 42.12 summarizes the recommended pharmacologic treatments of hypertension in pregnancy and preeclampsia. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers interfere with renal development in the fetus and should not be used in pregnancy. Although proteinuria may lessen as the blood pressure falls, renal function usually does not improve, and the mother remains at risk for development of the HELLP syndrome and the fetus for intrauterine death or placental abruption. Abrupt falls in blood pressure produced by medication may produce renal cortical necrosis.

Common Medications Used in the Treatment of Hypertension in Preeclampsia		
Type of Hypertension	Drug	Treatment Regimen
Acute	Hydralazine	5-mg 1V bolus every 20–30 min to maximum of 20 mg, then infusion at 5–10 mg/h
	Labetalol	50 mg 1V every 20 min to maximum 300 mg
	Nifedipine SR	20 mg oral
Chronic	First-line choice	Methyldopa 500–2000 mg/day PO
		Clonidine 0.2–0.8 mg/day PO
		Oxprenolol 80–480 mg/day PO
		Labetalol 200–1200 mg/day PO
		Atenolol 50–100 mg/day PO
	Second-line choice	Hydralazine 25–200 mg/day PO
		Prazosin 1–10 mg/day PO
		Nifedipine SR 40–100 mg/day PO

Figure 42.12 Common medications in the treatment of hypertension in preeclampsia. Diuretics and propranolol are not recommended. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are contraindicated. SR, sustained release.

Infusions of magnesium sulfate are effective in preventing epileptic seizures and lowering blood pressure. At high concentrations, magnesium ions depress the respiratory center, and magnesium infusions should not be given if the deep tendon reflexes (e.g., patellar reflex) cannot be elicited. Intravenous dexamethasone is suggested to hasten recovery in HELLP syndrome, but this has not been confirmed by larger studies.⁴⁰ Platelet transfusions are indicated if there is significant maternal bleeding or if platelet counts are less than $20 \times 10^9/L$.

ACUTE KIDNEY INJURY IN PREGNANCY

Acute kidney injury (AKI) in association with pregnancy, a rare complication in developed countries, is also decreasing in incidence in the developing world.⁴¹ Recent estimates suggest that the incidence of AKI from obstetric causes is less than 1 in 20,000 pregnancies.⁴² When AKI occurs early in pregnancy (12 to 18 weeks), it is usually in association with septic abortion or volume depletion due to hyperemesis gravidarum. Pregnancy confers a peculiar susceptibility to the vascular effects of gram-negative endotoxin (Shwartzman phenomenon). Perhaps because of the physiologic increase in procoagulant factors that occurs in normal pregnancy, the thrombotic microangiopathy and renal cortical necrosis that characterize septic shock, especially with gram-negative organisms, are particularly pronounced during pregnancy. Renal cortical necrosis is a common complication, for example, of septic abortion.

Most cases of AKI in pregnancy occur between gestational week 35 and the puerperium and are primarily due to preeclampsia and bleeding complications associated with placental abruption or other causes of obstetric hemorrhage. HELLP is also an important cause of AKI in pregnancy,⁴³ especially if it is not treated promptly by delivery. On occasion, nonsteroidal anti-inflammatory agents, used for postpartum analgesia, may precipitate AKI in patients who are volume depleted from hemorrhage, decreased fluid intake, or both. In severe cases of obstetric hemorrhage, acute cortical necrosis with associated disseminated intravascular coagulation may be present, and

ultrasound or computed tomography may demonstrate hyper-echoic or hypodense areas in the renal cortex.

General Management of Acute Kidney Injury in Pregnancy

The key issue in management of AKI in pregnancy is restoration of fluid volume deficits and, in later pregnancy, delivery of the baby and placenta as quickly as possible. No specific therapy is effective in acute cortical necrosis. Most patients with acute cortical necrosis ultimately require dialysis that may be permanent, but 20% to 40% have partial recovery of renal function. Both peritoneal dialysis and hemodialysis have been used during pregnancy, but peritoneal dialysis carries the risk of impairing utero-placental blood flow.

Hemolytic-Uremic Syndrome and Thrombotic Thrombocytopenic Purpura

Although rare, thrombotic microangiopathy due to hemolytic-uremic syndrome (HUS) or thrombotic thrombocytopenic purpura (TTP) is an important cause of pregnancy-associated AKI, with considerable morbidity. Thrombotic microangiopathy shares several clinical and laboratory features of pregnancy-specific disorders, such as the HELLP variant of preeclampsia and acute fatty liver of pregnancy; thus, distinction of these syndromes is important for therapeutic and prognostic reasons.

Features that may be helpful in making the correct diagnosis include timing of onset and the pattern of laboratory abnormalities (Fig. 42.13). HELLP syndrome typically develops in the third trimester; only a few cases have developed in the

postpartum period, usually within a few days of delivery. In contrast, the symptoms of HUS-TTP may begin antepartum, but most cases are diagnosed postpartum. Preeclampsia-HELLP syndrome is much more common than HUS-TTP, and it is usually preceded by hypertension and proteinuria. Renal failure is unusual in women with HELLP syndrome, even with severe cases, unless significant bleeding or hemodynamic instability or marked disseminated intravascular coagulation occurs. HELLP syndrome recovers with delivery, whereas HUS-TTP is often associated with persistent renal impairment and hypertension, with many requiring dialysis or transplantation long term.⁴⁴ Another laboratory feature of preeclampsia-HELLP syndrome that is not usually associated with HUS-TTP is marked elevation in liver enzymes. The presence of fever is more consistent with a diagnosis of TTP than of preeclampsia or HUS. Treatment of HUS-TTP includes plasma infusion or exchange and other modalities used in nonpregnant patients with these disorders. The management is discussed further in Chapter 28.

ACUTE FATTY LIVER OF PREGNANCY

Acute fatty liver of pregnancy (AFLP) is an extremely rare complication characterized by rapidly progressive liver failure that is estimated to occur in about 1 in 10,000 pregnancies. Women usually present with nausea, vomiting, and anorexia, and many have clinical and laboratory features that overlap with preeclampsia or HELLP syndrome (see Fig. 42.13). In addition to marked elevations in bilirubin, alanine transaminase, and aspartate transaminase, other frequently observed abnormalities include hypofibrinogenemia, prolonged partial thromboplastin time, hypoglycemia, anemia, and low platelet count. AKI occurs more commonly in AFLP than in the HELLP syndrome.⁴⁵ Because a defect in mitochondrial fatty acid oxidation due to mutations in the long-chain 3-hydroxyacyl-CoA dehydrogenase has recently been hypothesized as a risk factor for the development of fatty liver of pregnancy,⁴⁶ it is possible that the kidney dysfunction associated with AFLP reflects inhibition of β -oxidation of fats in the kidney. The histologic abnormalities are swollen hepatocytes filled with microvesicular fat and minimal hepatocellular necrosis. Delivery is urgently required, and most patients improve shortly afterward. This disorder was formerly associated with a more ominous outcome, which may have been a consequence of late diagnosis, although maternal mortality was two of six cases in a recent case series.⁴⁷

Pregnancy with Preexisting Kidney Disease

Mark A. Brown

Historically, renal disease was considered a contraindication to pregnancy, but now many pregnant women with chronic kidney disease (CKD) have successful outcomes. Accordingly, nephrologists and obstetricians need to be skilled in the management and counseling of such women.

THE ADVERSE EFFECTS OF CHRONIC KIDNEY DISEASE ON PREGNANCY

Up to 3% to 10% of women of childbearing age have CKD stages 3 to 5.¹ Available data on pregnancy outcomes are mainly from studies published 10 to 20 years ago²⁻⁴ and probably overestimate risk compared with outcomes achieved with modern care, particularly with improvements in neonatal intensive care. The key pre-pregnancy factors predicting outcome include:

- Degree of renal impairment.
- Control of hypertension before pregnancy.
- Degree of proteinuria.

In most circumstances, these features are more important than the mother's specific renal disease in predicting outcome.

Most women with mild renal impairment (serum creatinine concentration <1.5 mg/dl [130 μ mol/l]) and controlled hypertension have a successful pregnancy outcome. Preexisting hypertension is probably the main predictor of pregnancy outcome in women with mild renal impairment.

In contrast, those with moderate (serum creatinine concentration of 1.5 to 2.5 mg/dl [130 to 220 μ mol/l]) to severe (>2.5 mg/dl [220 μ mol/l]) renal impairment, particularly when it is accompanied by hypertension and heavy proteinuria, have a lower chance of having a live baby and a greater risk for maternal complications, including progression of the renal disease (Fig. 43.1).

Control of Hypertension

A retrospective analysis of 358 pregnant women with CKD in the United Kingdom found an association between diastolic blood pressure (BP) above 90 mm Hg (treated or untreated) and neonatal death. This relatively mild degree of hypertension also compounded the risk of preterm birth that arises from renal impairment alone.⁵

Progression of Chronic Kidney Disease

The risk of progression of renal disease during pregnancy likewise depends less on the specific renal disorder but more on:

- Baseline serum creatinine concentration.
- Control of hypertension.

- Increasing proteinuria or the onset of superimposed preeclampsia.

The natural history of most CKD is that accelerated deterioration during a pregnancy is unlikely, the main exception being systemic lupus, which can flare, leading to worsening renal disease during the pregnancy. However, 50% of women with moderate renal impairment (serum creatinine >1.5 mg/dl [130 μ mol/l]) have a significant rise in serum creatinine in the third trimester or early postpartum, and if this occurs, almost one in five progresses to end-stage renal disease within 6 months after delivery.

Prematurity or Fetal Growth Restriction

Prematurity, fetal growth restriction, and stillbirth are the major concerns for pregnancies of women with renal impairment, particularly if superimposed preeclampsia develops. Uncontrolled hypertension at conception is a poor prognostic feature in terms of fetal outcome (Fig. 43.2).

Fertility

Fertility rate is reduced in women with moderate to severe renal impairment, but there are no precise estimates. Because even women on dialysis may become pregnant, all should be advised to use contraception unless planning a pregnancy.

MANAGEMENT COMMON TO ALL PREGNANCY WITH PREEXISTING KIDNEY DISEASE

The principles of management of pregnancy in women with CKD are summarized in Figure 43.3.

Pre-Pregnancy Counseling

Any woman with CKD stages 3 to 5 should receive pre-pregnancy counseling. So should women with CKD stages 1 and 2 if they have hypertension, significant proteinuria, poor obstetric history, recurrent urine infections, inheritable renal disease, or diseases (e.g., systemic lupus) likely to worsen during pregnancy. Issues that should be covered in counseling are shown in Figure 43.4.

Excretory Renal Function

Glomerular filtration rate (GFR) rises by about 50% during normal pregnancy, typically apparent by the end of the first trimester (see Chapter 41). Serum creatinine above 1 mg/dl (88 μ mol/l) in a pregnant woman generally indicates reduced

Renal Outcomes According to Pre-Pregnancy Serum Creatinine

Creatinine < 1.5 mg/dl (130 μ mol/l)

- Permanent loss of GFR in <10% of women
- Major determinant of ESRD progression is hypertension

Creatinine 1.5–2.5 mg/dl (130–220 μ mol/l)

- Decline or permanent loss of GFR in 30% of women
- Increased to 50% if uncontrolled hypertension
- 10% ESRD soon after pregnancy

Creatinine > 2.5 mg/dl (220 μ mol/l)

- Progression to ESRD highly likely during or soon after pregnancy

Figure 43.1 Renal outcomes according to pre-pregnancy serum creatinine. ESRD, end-stage renal disease; GFR, glomerular filtration rate.

Fetal Outcomes According to Maternal Serum Creatinine Before Pregnancy

Outcomes after accounting for first-trimester miscarriage

Creatinine < 1.5 mg/dl (130 μ mol/l)

- Live births in >90% of women

Creatinine 1.5–2.5 mg/dl (130–220 μ mol/l)

- Live births in about 85% of women unless uncontrolled hypertension (MAP >105) at conception
- 60% prematurity - mainly iatrogenic (preeclampsia/fetal growth restriction)

Creatinine > 2.5 mg/dl (220 μ mol/l)

- Fetal loss high - estimates uncertain

Figure 43.2 Fetal outcomes according to maternal serum creatinine before pregnancy. MAP, mean arterial pressure.

Principles of Antenatal Care with Preexisting CKD

- Management of hypertension aiming for BP 110-140/80-90 mm Hg
- Use aspirin (75–150 mg/day) if creatinine \geq 1.5 mg/dl (130 μ mol/l)
- Correct interpretation and management of changes in serum creatinine
- Measurement, interpretation, and management of proteinuria, including nephrotic syndrome – use heparin prophylaxis if nephrotic
- Identification and management of urinary tract infection
- Clinical assessment and maintenance of volume homeostasis
- Consideration of appropriate “renal” and antihypertensive medications throughout pregnancy – cease statins, ACEI, and ARB
- Identification of superimposed preeclampsia
- Assessment of fetal well-being – review at each visit whether there are indications for delivery (see fig 43.5)
- Consideration of the primary underlying renal disease and its peculiar problems

Figure 43.3 Principles of antenatal care with preexisting CKD. ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BP, blood pressure; GFR, glomerular filtration rate.

Pre-pregnancy Counseling in CKD

Maternal risks

Accelerated decline in GFR, sometimes precipitating dialysis during pregnancy or soon after
Severe maternal hypertension
Superimposed preeclampsia with renal, hepatic, thrombotic, or bleeding and neurologic risks
Nephrotic syndrome with risks of thrombosis or sepsis

Fetal risks

Fetal growth restriction or intrauterine fetal death due to placental insufficiency
Prematurity
Complications of drug therapy for renal disease during pregnancy
Inheritance of a renal disorder

Figure 43.4 Pre-pregnancy counseling in CKD. Issue that should be discussed at pre-pregnancy counseling for women with CKD. GFR, glomerular filtration rate.

GFR. The Modification of Diet in Renal Disease (MDRD) study equation or other formulae that estimate GFR are not valid for pregnancy. Measurement of creatinine clearance requires 24-hour urine collection, which is cumbersome; and even when it is conducted diligently, it may be inaccurate because of ureteral dilation, which results in pooling of urine and an incomplete collection. Serum cystatin C is being evaluated, but serum creatinine remains the standard for assessment of GFR during pregnancy.

The limited outcome data for pregnancy with kidney disease are mainly derived from studies using serum creatinine.

Blood Urea Nitrogen

Increments in blood urea nitrogen (BUN) and creatinine may indicate deteriorating GFR and point to the need for initiation of dialysis if the pregnancy is to have any chance of success (see later, [Dialysis in Pregnancy](#)). However, a rising BUN concentration, particularly when it is accompanied by rising hemoglobin or hematocrit, may represent intravascular contraction, typically seen in preeclampsia.

Serum Electrolytes, Albumin, and Volume Homeostasis

Plasma sodium and bicarbonate are slightly reduced, potassium is at the lower end of the normal range, and albumin and urate are lower than in the nonpregnant state. Increases in plasma sodium to levels of nonpregnant women should raise the possibility of (reversible) pregnancy-specific diabetes insipidus (due to excess placental vasopressinase). In general, this is a mild disorder, but DDAVP should be given if plasma sodium rises above 150 mmol/l.

Adequate intravascular volume is essential to preservation of GFR and good pregnancy outcome for mother and baby. Clinically, it is difficult to assess maternal volume homeostasis. Edema is an unhelpful sign in pregnancy, so hematocrit should be measured in women with underlying CKD at the initial first-trimester visit, along with serum albumin. Both measures should fall slightly as pregnancy progresses. A rise in either value strongly suggests intravascular volume contraction, although there is

no absolute discriminant value. Conversely, a significant fall in either value does not by itself diagnose excessive volume expansion because the hematocrit depends on other factors, and serum albumin may fall in patients with nephrotic syndrome, who in turn may have reduced intravascular volume.

In practice, volume excess, provided there is no respiratory compromise and BP can be controlled, is more favorable than volume depletion for maternal renal function and fetal growth.

When there is concern about fetal growth or deteriorating GFR in women with CKD and reduced intravascular volume is suggested by the change in hematocrit and albumin from baseline, a trial of intravenous normal saline (no more than 1 liter) under observation in the hospital is a reasonable clinical approach.

Urinalysis

A dipstick test result of “negative” or “trace” protein in most (but not all) cases excludes true proteinuria. Any woman with 1+ (0.3 g/l) proteinuria or above should have formal quantification of protein excretion with either a spot urine protein to creatinine (PC) ratio or a 24-hour urine collection.

Glycosuria may be normal and is not diagnostic of diabetes mellitus. However, when glycosuria is detected in early pregnancy in a woman with CKD, a formal 75-g oral glucose tolerance test should be arranged.

Dipstick hematuria during pregnancy is common and often resolves after delivery. Provided there is no urinary tract infection, urine sediment is inactive, and serum creatinine concentration is normal, this is not associated with adverse maternal or fetal outcomes during pregnancy and can be investigated if it is persistent postpartum.⁶ Pregnancy may be the first time a woman's urine is examined, so previously undetected renal disorders may be diagnosed.

Proteinuria and Nephrotic Syndrome

In the nonpregnant woman, daily protein excretion is generally less than 150 mg/day, composed of up to 20 mg/day albumin and the remainder of other proteins, often of tubular origin.⁷ Albumin excretion during normal pregnancy is unchanged, but total protein excretion is increased in normal pregnancy, predominantly because of an increase in the porosity of the glomerular basement membrane, through unknown mechanisms.⁷ The upper limit of normal protein excretion during pregnancy is defined as 300 mg/day. In a midstream specimen of urine, a PC ratio above 30 mg/mmol (0.3 mg/mg) correlates with proteinuria of more than 300 mg/day.⁸

New-Onset Proteinuria

Isolated non-nephrotic proteinuria may develop *de novo* during pregnancy.⁹ In these cases, in which GFR is normal, one of three scenarios usually unfolds:

1. Preeclampsia is subsequently evident.
2. No pregnancy complications occur, and the proteinuria disappears postpartum.
3. Intrinsic glomerular disease has developed and remains postpartum. In my experience, this is an uncommon event.

Preexisting Proteinuria

Although the spot urine PC ratio in pregnancy is a reasonably reliable method of determining whether protein excretion is abnormal, there have been no studies to date to show that serial measurements of urine PC ratio reliably predict *changes* in

proteinuria. A practical approach is to measure 24-hour urinary protein and creatinine excretion and to determine the PC ratio at the early pregnancy visit; subsequent PC ratios will give a guide to that woman's protein excretion.

When there is a true increase in protein excretion during pregnancy in women with underlying renal disease, there are few therapeutic options apart from ensuring BP control (see later).

Nephrotic Syndrome

The one situation in which 24-hour urinary protein excretion should be measured in these women is to diagnose nephrotic syndrome. Because serum albumin concentration falls in most pregnancies because of volume expansion and is often below 30 g/l, this is not a reliable indicator of nephrotic syndrome. A spot urine PC ratio above 230 mg/mmol indicates that protein excretion is above 3 g/day,¹⁰ and this should be confirmed with measurement of 24-hour urinary protein. These women will generally have edema, but this is unhelpful as it occurs in two thirds of normal pregnancies. Although a rise in serum cholesterol level is typical of nephrotic syndrome, this may occur during normal pregnancy.

Confirmation of true nephrotic syndrome has important implications in pregnancy. There will be urinary loss of vitamin D-binding protein, transferrin, immunoglobulins, and antithrombin III (accompanied by increased hepatic synthesis of clotting factors) and a propensity for intravascular volume contraction. These changes can result in calcium deficiency, iron deficiency, increased likelihood of infection, thrombosis and reduced uteroplacental blood flow with fetal growth restriction or death,¹¹ and sometimes reduced renal blood flow with worsening renal function. Treatment requires oral calcium, vitamin D, and iron supplementation and subcutaneous heparin for thrombosis prophylaxis, ensuring adequate fetal growth and amniotic fluid by ultrasound and reassessment of maternal serum creatinine concentration on a regular basis. If nephrotic syndrome occurs early in pregnancy, I add vitamin D for prophylaxis against osteoporosis, although there are no controlled trials to test this practice.

Hypertension

Hypertension in pregnancy is defined as BP above 140/90 mm Hg, and this is generally the threshold for treatment, with an acceptable range on treatment of 110 to 140/80 to 90 mm Hg. This range of treatment is not based on solid pregnancy outcome data but is thought to be the range that reduces maternal risk for severe hypertension while providing sufficient systemic BP to maintain placental perfusion. Because the target BP for nonpregnant women with CKD is less than 130/80 mm Hg (or <125/75 mm Hg with proteinuria >1 g/day), a woman with CKD may have a period of 40 weeks or so when BP is above usual target, which may contribute to progressive renal impairment after the pregnancy. Nevertheless, if a pregnant woman develops BP below 110/80 mm Hg, it is my practice to reduce antihypertensives to avoid the risk of fetal hypoperfusion.

Most pregnant women with CKD will not exhibit the usual early fall in BP, and in many, BP increases as the pregnancy progresses. Why this occurs is not entirely clear. Normal pregnancy is accompanied by significant volume expansion that does not usually induce hypertension. However, in CKD, there is often inability to excrete a sodium load with accompanying hypertension, and it is likely that this mechanism contributes in pregnancy. Other factors almost certainly playing a role in this

hypertension include stimulation of the renin-angiotensin and sympathetic nervous systems; alterations in endothelial factors, such as prostacyclin, nitric oxide, and endothelin; and particularly in transplant patients, the drugs used, such as calcineurin inhibitors and corticosteroids. Regardless of its cause, persistence of hypertension is an adverse factor in pregnancy outcome.¹² Fear of using antihypertensives in pregnancy has been associated with poorer pregnancy outcomes, at least in women with renal transplants.¹³

BP will often rise significantly soon after delivery. Therefore, BP measurement and treatment should be undertaken diligently in the early postpartum period.

Control of BP is imperative to successful pregnancy outcome in women with underlying renal disease. Diuretics are not recommended during pregnancy as any reduction in maternal plasma volume may have adverse effects on uteroplacental or renal perfusion. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) must be discontinued, preferably before pregnancy but certainly as soon as pregnancy is diagnosed because of increased risks of fetal growth restriction, oligohydramnios, neonatal renal failure, and probably cardiac and neurologic development abnormalities. Aldosterone antagonists should also be avoided. Atenolol has been associated with fetal growth restriction. Suitable antihypertensives include methyldopa, labetalol, oxprenolol, hydralazine, and nifedipine, and they may all be used in conventional doses. Diltiazem may also have a small benefit.

Superimposed Preeclampsia

Preeclampsia (see Chapter 42) is a placental disorder of unknown etiology that has several predisposing risk factors, one of which is CKD. The maternal renal effects of preeclampsia include a reduction in renal blood flow, increased sodium and uric acid reabsorption, reduced circulating renin and aldosterone concentrations, proteinuria, and impaired GFR.¹⁴

Superimposed preeclampsia in a woman with underlying renal impairment will lead to worsening renal function; exaggerated hypertension and proteinuria with risks of nephrotic syndrome; short-term and long-term risks to maternal renal function; and increased risks for fetal growth restriction, prematurity, and perinatal mortality.

However, it is difficult to diagnose superimposed preeclampsia in a woman who begins her pregnancy with renal impairment or proteinuria. An increase in BP, decline in GFR, increased serum urate, or increasing protein excretion can all be due to progression of the underlying renal disorder rather than superimposed preeclampsia, and as yet there is no definitive diagnostic test. However, when these features are accompanied by neurologic signs such as hyperreflexia with clonus or by abnormal liver transaminases or new-onset thrombocytopenia (except in systemic lupus), it is highly likely that superimposed preeclampsia has developed. Typically, these changes occur after 20 weeks of gestation.

Diagnosis of superimposed preeclampsia is to some extent an academic exercise as clinicians managing the woman with underlying renal disease should be vigilant for changes in maternal and fetal condition in all cases, and the indications for delivery in women with preeclampsia are broadly the same as those in women with progressive underlying renal disease (Fig. 43.5).

Limited studies suggest that aspirin is of benefit in reducing superimposed preeclampsia and perinatal death in women with

Indications for Delivery in Women with Pre-Eclampsia or Chronic Kidney Disease

Inability to control blood pressure
Deteriorating GFR with no reversible component
Neurological abnormalities
Worsening thrombocytopenia
Increasing liver transaminases
Failure of fetal growth

Figure 43.5 Indications for delivery in women with preeclampsia or CKD. GFR, glomerular filtration rate.

underlying renal disease; the number needed to treat was between 9 and 57 for prevention of preeclampsia and between 42 and 357 to prevent perinatal death.¹⁵ The PARIS study also found that aspirin reduced superimposed preeclampsia in women with underlying renal disease (RR 0.63, 0.38-1.06), but only 450 women were included in this analysis.¹⁶ My practice is to use low-dose aspirin (150 mg/day) for all women with CKD and serum creatinine above 1.5 mg/dl (130 μ mol/l) or for those with lower serum creatinine who have had early-onset severe preeclampsia or fetal loss in a previous pregnancy; the effects of this dose of aspirin on renal function are minimal, and this is generally a safe approach.

RENAL BIOPSY IN PREGNANCY

It is rare for renal biopsy to be required in pregnancy. After 32 weeks of gestation, if the renal state has changed so much that biopsy is considered necessary to guide treatment, it is better to deliver the baby and to manage the renal disease outside of pregnancy. Situations in which biopsy may provide information that could have a significant impact on the pregnancy outcome for mother and baby are the following:

1. *De novo* onset of nephrotic-range proteinuria or unexplained impaired GFR with abnormal urine sediment before fetal viability, that is, before 24 weeks of gestation. Nephrotic syndrome after this stage can generally be managed conservatively until delivery usually at about 32 weeks. Most such cases are due to preeclampsia.
2. Before 32 weeks of gestation when the clinician and patient have agreed that immunosuppression or plasma exchange will be used if necessary while prolonging the pregnancy to about 32 weeks: rapidly declining GFR without any apparent reversible cause in women with underlying primary glomerulonephritis; acute kidney injury with active urine sediment; and declining GFR or increasing proteinuria in a woman with lupus nephritis or lupus without previously known nephritis.
3. Deteriorating GFR before 32 weeks of gestation without obvious cause in a woman with a kidney transplant to exclude acute rejection.

The usual technique of renal biopsy (see Chapter 6) can be applied in pregnancy, although the sitting position rather than the supine position is better tolerated in the second trimester onward. Complication rates of renal biopsy in pregnancy are similar to those in general nephrology practice.¹⁷

ASSESSMENT OF FETAL WELL-BEING

An early pregnancy ultrasound is invaluable in accurately dating the expected birth. The next usual assessment is a fetal morphology scan at 18 to 20 weeks of gestation to confirm gestational age, to screen for fetal anomaly, to assess fetal well-being, and to check placental position. In women with CKD stages 3 to 5, this is followed by regular ultrasound examinations at 2- to 4-week intervals to assess fetal growth and the volume of amniotic fluid as well as by Doppler studies of umbilical artery blood flow. More recently, the combination of tests at 12 weeks of gestation for pregnancy-associated plasma protein A, inhibin, human chorionic gonadotropin, and alpha-fetoprotein with measurement of uterine artery pulsatility index at 20 weeks of gestation has provided a good negative predictive test for fetal outcome in women with high-risk pregnancies, although these studies are not specific for women with underlying renal disease.

Asymmetric intrauterine growth restriction [IUGR], in which the abdominal measurements are more decreased than the fetal head and femur measurements, is characteristic of IUGR related to maternal CKD.

Amniotic fluid volume correlates well with perinatal outcome, and a low amniotic fluid index helps distinguish babies small because of IUGR from those that are constitutionally small. Mid-trimester severe oligohydramnios is associated with very poor outcome; it indicates nonfunctioning fetal kidneys and usually also leads to pulmonary hypoplasia and limb contractures.

Absent end-diastolic flow on umbilical artery velocimetry is usually an indication for delivery, depending on gestation. The development of reversed end-diastolic flow flags a high risk of fetal hypoxia, acidosis, and death.

Fetal assessment by one or more of these means should be carried out regularly throughout pregnancy and particularly in the third trimester.

TIMING OF DELIVERY

In women with stable CKD and no evidence of fetal compromise, pregnancies can be continued to term and spontaneous labor awaited. The method of delivery, either vaginal or by cesarean section, is normally determined by other issues (such as previous cesarean section, presentation, or previous poor obstetric history) rather than by the presence of CKD *per se*. The usual indications for delivery are listed in Figure 43.5.

The goal is to time delivery such that the risks of delivery (to both mother and fetus) are less than the risks if the pregnancy continues. This is often a difficult and individual decision requiring consultation among nephrologist or obstetric medicine physician, obstetrician, midwife, and neonatologist. The following issues need to be considered:

1. Gestational age is the most important determinant of outcome. Decisions are difficult to make at the borderlines of viability (23 to 25 weeks of gestation). Although outcome data vary from country to country, approximate survival rates increase from 30% at 23 weeks to 65% at 25 weeks to 95% at 30 weeks of gestation. Babies born before 30 weeks of gestation have significant risks of long-term morbidity, including chronic lung disease and cerebral palsy.
2. The most common problem faced by preterm babies is respiratory distress syndrome. Maternally administered antenatal corticosteroids, generally intramuscular betamethasone (11.4 mg, two doses 12 hours apart), have been

shown to reduce respiratory distress syndrome by 50%. For best effect, the corticosteroids need to be administered at least 24 hours before delivery.

3. There is less neonatal morbidity and mortality if babies are born in hospitals where there is appropriate neonatal care rather than being transferred after delivery. Thus, if preterm delivery is likely, transfer of the mother to an appropriate unit before delivery should be considered.

Whereas these pregnancies are certainly high risk compared with the normal pregnant woman, it is important for clinicians and midwives to remember that the final pregnancy outcome in most cases is successful for both mother and baby. Clinicians can take a positive approach, at all times emphasizing the need for diligence and assessment for potential complications but highlighting that the end result in most cases will be good, in turn helping to relieve some of the stress that accompanies pregnancy for these women.

MANAGEMENT OF SPECIFIC RENAL DISORDERS DURING PREGNANCY

The most common chronic kidney diseases predating pregnancy are primary glomerulonephritis (usually IgA nephropathy or focal segmental glomerulosclerosis), diabetic nephropathy, lupus nephritis, and reflux nephropathy.

IgA Nephropathy

Long-term follow-up of childhood IgA nephropathy showed that later pregnancy was complicated by hypertension in half the cases and prematurity in one third,¹⁸ but these outcomes are not peculiar to this renal disease. Rare cases are familial, in which case the pregnant woman should be advised to have her child screened by urinalysis in the first few years of life. Macroscopic hematuria is no more likely during pregnancy unless there is intervening respiratory or gastrointestinal tract infection. IgA nephropathy should be managed like other CKD during pregnancy.

Diabetic Nephropathy

Recent data in the United Kingdom found that 8% of pregnant women with type 1 diabetes and 5% of those with type 2 diabetes had nephropathy.¹⁹ Diabetes *per se* increases risks for preterm birth, cesarean section, and perinatal mortality. The presence of overt nephropathy more than doubles the risk of fetal death after 20 weeks. There is an added risk for congenital abnormalities if blood glucose concentration was not adequately controlled at the time of conception.

The Diabetes Control and Complications Trial and the EURODIAB study both concluded that pregnancy does not increase the progression of diabetes to early diabetic nephropathy (microalbuminuria).^{20,21} Whereas microalbuminuria alone did not correlate with increased perinatal risk, both prematurity and superimposed preeclampsia rates were higher than in type 1 diabetics without microalbuminuria.

The outcome of established diabetic nephropathy during pregnancy depends on the usual factors of preexisting renal impairment and control of hypertension. Meticulous control is required of both blood glucose concentration and BP during pregnancy in women with early or overt diabetic nephropathy. One study showed that failure to achieve mean arterial pressure

of less than 100 mm Hg was associated with increased risk of early delivery even after adjustment for glucose control.²² Ideally, ACE inhibitors should be introduced soon after delivery for prevention of progression of diabetic nephropathy; at least captopril is safe during breast-feeding.

Lupus Nephritis

Women with lupus nephritis should have quiescent disease at conception to offer the best chance of a successful pregnancy outcome. Those with active disease at conception have a higher likelihood for development of acute lupus nephritis during pregnancy, which is then associated with high fetal risk. Ideally, women with lupus should be in remission for about 12 months before conception and on maintenance corticosteroids in doses less than prednisolone 20 mg/day. In such women, the prior histologic class of lupus nephritis has no influence on pregnancy outcome. Hydroxychloroquine may be continued during pregnancy.

New onset or a flare of lupus nephritis, evidenced by increasing proteinuria, active urine sediment, and rising serum creatinine concentration, is a major concern, and such cases have sometimes been associated with maternal death. These women, with new onset or a flare of lupus nephritis, should be treated by increasing doses of prednisolone with the early introduction of azathioprine. Some prefer to undertake renal biopsy at this point to confirm the histologic changes before introducing immunosuppression. Either approach is reasonable, but my approach is to introduce corticosteroids and azathioprine and to reserve biopsy for after delivery.

Other women with known lupus nephritis in remission before conception should remain on their low-dose prednisolone and azathioprine throughout pregnancy. Cyclophosphamide is contraindicated in pregnancy because of teratogenicity; although it has been used successfully in a few cases of lupus nephritis, its use is not recommended.

Lupus nephritis may develop or flare in the postpartum period, but prophylactic corticosteroid therapy in those who have not had a flare during the pregnancy is not indicated. The major cause of maternal death in lupus nephritis is sepsis, and immunosuppression should be used with care in pregnant women.²³

Reflux Nephropathy

As for other renal disorders, the outcome of pregnancies in women with reflux nephropathy depends on the preexisting renal function and control of BP rather than on the disorder itself. Approximately one in four may develop preeclampsia, and about 40% of offspring have vesicoureteral reflux. These women are more predisposed to urinary tract infection throughout pregnancy, as are women who have had surgically corrected reflux in childhood.²⁴ Around 20% of women with reflux nephropathy will develop urinary tract infection in pregnancy,²⁵ with about 6% of these due to acute pyelonephritis. Significant urinary tract infection can be associated with premature labor or spontaneous rupture of membranes. Regular urine culture should be obtained throughout pregnancy in women with underlying reflux nephropathy.

Inherited Renal Disorders

Inherited renal disorders are likely to have been diagnosed before the pregnancy, and the specific implications of this for the off-

spring will have been discussed. The most common is autosomal dominant polycystic kidney disease. Others include Alport's syndrome and familial hyperuricemic nephropathy.

Reflux nephropathy is not inherited by specific mendelian traits but tends to cosegregate within families, and the pregnant woman needs to be aware of this.

Fetal renal anomalies are usually identified at the time of routine ultrasound screening or during evaluation of a fetus from a family with a known hereditary renal disorder. Invasive procedures, such as chorionic villus sampling for DNA analysis, are rarely informative and should be undertaken only after advice from a clinical geneticist.

RECURRENT URINARY TRACT INFECTION

Urinary tract infection during pregnancy develops more readily into acute pyelonephritis and is generally of greater consequence than in the nonpregnant state.

Asymptomatic bacteriuria occurs in 2% to 10% of pregnancies and is associated with preterm labor, IUGR, and perinatal mortality. In the normal nongravid woman, asymptomatic bacteriuria rarely progresses to cystitis. In pregnancy, however, the chance for development of overt infection is much greater, with rates of acute pyelonephritis complicating asymptomatic bacteriuria reported as high as 40%. If asymptomatic bacteriuria is treated in pregnant women, this risk is reduced to below 10%. The range of organisms causing urinary tract infection in pregnancy does not differ from that outside of pregnancy; *Escherichia coli* causes approximately 90% of infections.

Standard antenatal care should include culture of a midstream specimen of urine early in the pregnancy. In those with abnormal urinary tract structure, a history of recurrent urinary tract infection, CKD, or diabetes, further regular cultures are required. Women who have threatened premature labor should have further urine cultures even without symptoms suggestive of urinary tract infection. Treatment of bacteriuria has been proved beneficial in a number of randomized controlled studies²⁶; 3 days of treatment is recommended for treating and eradicating bacteriuria. Amoxicillin resistance is relatively common; it should be replaced by cephalexin, amoxicillin-clavulanic acid, trimethoprim, or nitrofurantoin (Fig. 43.6).

Women with a history of recurrent urinary tract infection should have monthly urine cultures. For those with a predictable history of postcoital cystitis, postcoital single-dose cephalexin (250 mg) or nitrofurantoin (50 mg) can significantly reduce the likelihood of infection. For others with recurrent urinary tract infection before pregnancy, low-dose first-generation cephalosporins at night may help suppress further infections and therefore reduce the risks of pyelonephritis and premature labor. Any woman who has recurrent urinary tract infection before pregnancy should undergo ultrasound of the urinary tract before conception or in early pregnancy to exclude structural disease.

Prophylactic antibiotics should also be given to women with recurrent asymptomatic bacteriuria or infection during pregnancy. Nighttime cephalexin (250 mg) or nitrofurantoin (50 mg) is usually sufficient to prevent infection. Breakthrough infections should be treated with a 7-day course of antibiotics.

Pyelonephritis is usually uncomplicated but can cause bacteremia, anemia, respiratory insufficiency, renal impairment, and premature labor. In pregnancy, pyelonephritis should be managed initially in the hospital with intravenous fluids and intravenous antibiotics. Empiric antibiotics should include a cephalosporin and gentamicin added if this proves unsuccessful.

Figure 43.6 Antibiotic regimens for treatment of urinary tract infections in pregnancy. Local bacteriologic patterns and sensitivity results should influence which antibiotics are used.

Antibiotic Regimens for Treatment of Urinary Tract Infections in Pregnancy			
Acute Cystitis			
Amoxicillin	500 mg	Three times daily	3–7 days
Nitrofurantoin	100 mg	Twice daily	3–7 days
Cephalexin	500 mg	Two-three times daily	3–7 days
Asymptomatic Bacteriuria			
Cephalexin	500 mg	Three times daily	3 days
Amoxicillin	500 mg	Three times daily	3 days
Amoxicillin–clavulanic acid	500 mg	Three times daily	3 days
Nitrofurantoin	50 mg	Four times daily	3 days
Fosfomycin	3 g	Single dose	
Recurrent Bacteriuria or Cystitis			
Cephalexin		250 mg nighttime (or postcoital)	
Nitrofurantoin		50 mg nighttime (or postcoital)	
Amoxicillin		250 mg nighttime (or postcoital)	
Pyelonephritis (initial IV therapy)			
Ceftriaxone		1 g daily	
Ampicillin (with gentamicin)		1 g q6h	
Gentamicin		3 mg/kg daily	
Ticarcillin		3.2 g q8h	
Piperacillin		4 g q8h	

Pregnant women should continue oral antibiotic treatment after discharge for a further 10 to 14 days, then take a low-dose “suppressive” antibiotic until after delivery (see Fig. 43.6). In all cases of urinary tract infection in pregnancy, a follow-up urine culture 1 to 2 weeks after the antibiotic course is mandatory to exclude recurrent or persistent infection.

Cephalosporins, amoxicillin, trimethoprim, and nitrofurantoin are safe for treatment of urine infection during pregnancy, although trimethoprim can occasionally induce hyperkalemia in some women.

Gentamicin should be reserved for the treatment of severe pyelonephritis with systemic sepsis. It has been the practice to avoid quinolones because of teratogenic risks in animals, but data in humans suggest that they are safe and can be used when there is a compelling microbiologic reason.²⁷ Information on safety of antibiotics in pregnancy is also shown in Figure 42.2.

RENAL CALCULI IN PREGNANCY

Women with a history of metabolic abnormalities causing stone formation before pregnancy need their treatment modified during pregnancy. I advocate simply the adherence to a fluid intake of 2.5 to 3 liters per day and recommend that thiazides (for hypercalciuria), allopurinol (for hyperuricosuria), or captopril or penicillamine (for cystinuria) be discontinued. Fortunately, normal pregnancy is accompanied by increased urine pH, and this may help reduce uric acid or cystine stone formation.

Despite relative hypercalciuria and urinary stasis in pregnancy, pregnant women may be protected against renal calculi by the simultaneous increase in endogenous inhibitors of stone formation, such as urinary thiosulfate, which parallels hypercalciuria during gestation and returns to normal postpartum.

Because of concerns about irradiation from computed tomographic scanning and the uncertain utility of magnetic resonance imaging in this setting, ultrasound is the preferred investigation for renal colic in pregnancy, despite its poor sensitivity and specificity for stone diagnosis (on the order of 30% to 60%).

Definitive management of a calculus is usually best left until after delivery. Because ultrasound will almost always show pelviureteral dilation, which is a feature of normal pregnancy, systemic infection and acute kidney injury are the only indications for urgent decompression of an obstructed system by percutaneous nephrostomy. Conservative therapy with analgesia and hydration will result in spontaneous passage of a stone in the majority of cases. Extracorporeal shock wave lithotripsy is contraindicated as it is potentially deleterious to fetal hearing. If a surgical procedure is necessary, ureteroscopy with YAG laser lithotripsy has been used and is considered relatively safe in pregnancy.

THROMBOTIC MICROANGIOPATHIES

Thrombotic microangiopathies that can develop in pregnancy (i.e., thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, and the HELPP syndrome) are discussed in Chapters 28 and 42.

DIALYSIS IN PREGNANCY

There has been significant recent improvement in the outcome of pregnant women with renal disease requiring dialysis during pregnancy. Such pregnancies (mostly in women already on dialysis) now have a one in two chance of fetal survival, albeit with about 80% chance of prematurity.²⁸ These improved outcomes have been associated with more intensive dialysis regimens, and advances in neonatal care also allow survival for more premature and growth-restricted infants. Recommendations for managing hemodialysis during pregnancy are listed in Figure 43.7.

Initiating Dialysis for Progressive Chronic Kidney Disease

A key question is when to initiate dialysis in women who have advanced CKD but are not yet on dialysis at the time of

Managing Hemodialysis During Pregnancy

Pre-pregnancy

- Advise risks of pregnancy (miscarriage, fetal death, prematurity, fetal growth restriction, preeclampsia)
- Cease ACE inhibitors, ARB, or atenolol; ensure that any other medications are safe in pregnancy
- Use aspirin (75–150 mg/day)
- Folate 5 mg daily

During Pregnancy

- A minimum of 20 hours per week dialysis during a minimum of 4 sessions, aiming for predialysis BUN < 40 mg/dl (serum urea ~ 15 mmol/l)
- Maintenance of serum calcium with additional oral calcium and vitamin D and increased calcium dialysate, monitored with frequent calcium measures as occasionally placental production of vitamin D–like substances and PTHrP may lead to increased serum calcium
- Dietitian advice about adequate protein and nutrient intake
- Supplement with oral phosphate or increased dialysate phosphate if necessary
- Less aggressive use of oral and dialysate bicarbonate to maintain serum bicarbonate in the usual pregnancy range of 18 to 22 mmol/l
- Intravenous iron as required to ensure adequate iron stores
- ESAs at doses generally higher than needed before pregnancy to maintain hemoglobin 10–11 g/dl, with increased surveillance of blood pressure
- Dialysis heparin requirements are often increased because of the hypercoagulable state of pregnancy; this is not the situation for every pregnant woman and is assessed by monitoring dialysis adequacy and dialyser clotting

After Delivery

- Return to usual dialysis schedule immediately
- Readjust dry weight and antihypertensives weekly for 6 weeks

Figure 43.7 Managing hemodialysis during pregnancy. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; ESAs, erythropoiesis-stimulating agents; PTHrP, parathyroid hormone-related peptide.

conception. It is generally recommended to commence dialysis at estimated GFR 20 ml/min or BUN 50 mg/dl (serum urea 18 mmol/l) and to aim for predialysis BUN < 40 mg/dl (serum urea 15 mmol/l).^{2,29} The available data suggest that dialysis initiated during pregnancy is associated with greater likelihood of successful pregnancy than is continuation of maintenance dialysis, probably because of the benefits of residual renal function.

Women Already Needing Regular Dialysis

Women of childbearing age undergoing dialysis have around 1 in 20 chance of conceiving throughout their years on dialysis.³⁰ Women of childbearing age on maintenance dialysis therefore need to be counseled about adequate contraception, particularly in view of the fairly poor outcomes of these pregnancies.

Dialysis Regimens in Pregnancy

Reports of successful pregnancy outcomes, albeit with high rates of preterm delivery and polyhydramnios, generally include intensified hemodialysis or peritoneal dialysis schedules. Daily hemodialysis may be necessary to achieve the biochemical goal of predialysis BUN < 40 mg/dl (serum urea 15 mmol/l).

Nocturnal hemodialysis may allow improved dialysis clearances with greater hemodynamic stability.

More intensive dialysis improves phosphate control, phosphate binders become unnecessary, and additional oral phosphate or increased dialysate phosphate may be needed because of the intensified dialysis and the fetal requirements for phosphate.

There is little information concerning specific requirements of women on peritoneal dialysis during pregnancy. There is no need to switch from peritoneal dialysis to hemodialysis even as the uterus enlarges. Dialysis adequacy can be maintained throughout pregnancy, although a major risk is that peritonitis may provoke premature labor or premature rupture of membranes.

Other management necessary for a successful pregnancy outcome includes the following:

- Control of maternal BP, generally to 110 to 140/80 to 90 mm Hg. This is difficult to achieve in many cases. Despite minimal or even lack of endogenous renal function, there still appears to be volume expansion in women on maintenance hemodialysis who become pregnant, as evidenced by their anemia and fall in serum albumin. There are no data yet in pregnancy on newer means of assessing volume status in dialysis patients, such as ultrasound measurement of inferior vena cava diameter or bioimpedance measurements.
- Active management of anemia with iron and erythropoiesis-stimulating agents. Target hemoglobin level should be 10 to 11 g/dl.
- Detection and early treatment of sepsis, which in turn precipitates premature labor or premature rupture of membranes. For those with residual renal function, repeated urine cultures are justified to detect and to treat asymptomatic bacteriuria.
- There are ongoing trials concerning the potential benefit of progesterone or its metabolites for the prevention of preterm labor, although not specifically in dialysis patients. Reports of changes in serum progesterone during dialysis vary widely, from significant reduction even to an increase.

At least weekly surveillance of pregnant women on dialysis is required to optimize outcome; dialysis intensity should be increased as far as practically possible if biochemical goals are not achieved. Fetal monitoring should include at least 2- to 4-week ultrasound scanning from the time of fetal viability, around 24 weeks of gestation.

RENAL TRANSPLANTATION AND PREGNANCY

Successful renal transplantation is an excellent way of restoring fertility in women with end-stage renal disease. The key questions in relation to management of women with a renal transplant in pregnancy are whether the pregnancy will have any effects on graft survival and whether the fetus will suffer as a result of the transplant or the immunosuppressive drugs.

Women should be advised to wait 12 months after a successful renal transplantation before embarking on pregnancy to ensure stable transplant function and maintenance immunosuppression. This interval is not based on solid pregnancy outcome data but is a practical time for ensuring clinical stability after transplantation, having optimal BP control and stable immunosuppression.

Immunosuppressive drugs considered safe in the transplant patient³¹ include prednisolone, azathioprine, and cyclosporine.

Tacrolimus has been associated with neonatal hyperkalemia, but recent data support its safety.³² Mycophenolate is associated with embryotoxic effects and must be avoided in pregnancy.

A favorable view of pregnancy in women who have undergone successful renal transplantation is supported by observations in more than 3000 pregnancies from 2000 women mostly receiving azathioprine and prednisone.³³ About 15% of these pregnancies miscarried spontaneously, and of those going past the first trimester, pregnancy was successful in more than 90% of cases, provided hypertension or a decline in renal function had not occurred before 28 weeks of gestation, in which case successful pregnancy outcome was reduced to about 70%. Women with preconception serum creatinine below 1.4 mg/dl (125 μmol/l) had 96% pregnancy success, whereas those with higher serum creatinine level had a 75% success rate. In keeping with the data for all women with CKD, long-term decline in renal function occurred significantly more often (27%) in those with preconception serum creatinine above 1.4 mg/dl (125 μmol/l).

Hypertension, either accelerated from preexisting hypertension or *de novo* during pregnancy, is present in 58% to 72% of cases. Even with these relatively good outcomes, somewhere between 30% and 70% of women will have hypertension requiring treatment as the pregnancy progresses (sometimes superimposed preeclampsia). Fetal growth restriction occurs in 40% to 50% of cases, and preterm delivery occurs in as many as two thirds, with attendant long-term risks of prematurity.³⁴ Cesarean section is necessary in approximately half of cases.

The United States National Transplantation Pregnancy Registry³² reported in 2004 on the outcomes of 1125 women who had received kidney-alone transplants. As this is a voluntary registry, however, there is potential for reporting bias. The majority of women were taking cyclosporine or tacrolimus. The mean preconception serum creatinine was 1.4 mg/dl (125 μmol/l). Spontaneous abortion rates ranged from 12% to 24%, and 40% to 50% of surviving pregnancies were of low birth weight and 50% born preterm; 4% of babies had a birth defect. Graft loss within 2 years ranged from 4% to 13%. Twenty-four pregnancies were reported in women taking mycophenolate or sirolimus, 12 of which resulted in spontaneous abortion, raising concern about women taking these agents in pregnancy. Fetal risks for pregnancy in women with a renal transplant are summarized in Figure 43.8.

Graft and patient survivals are similar in those with and without any pregnancy as long as 15 years of follow-up. A post-pregnancy increase in serum creatinine concentration has been

associated with cyclosporine use, possibly because cyclosporine doses were increased during pregnancy as plasma levels fell, presumably due to the associated plasma volume expansion of pregnancy. It remains controversial whether cyclosporine or tacrolimus doses should be increased during pregnancy. It is not my practice to make dose adjustments unless there are marked deviations from the baseline blood level during pregnancy.

Acute transplant rejection is uncommon, reported in less than 1 in 20 cases. Presentation as acute graft dysfunction is not different in pregnancy; renal biopsy is required to confirm the diagnosis.

There is an increased risk of infection (20% to 35%), particularly urinary tract infection but also cytomegalovirus infection with attendant maternal and fetal risks. The consequences of any infection can include premature labor and preterm rupture of membranes.

Gestational diabetes occurs in 3% to 12% of these pregnancies, no more common in tacrolimus-treated women than in those receiving cyclosporine.

Recommendations remain uncertain about breast-feeding for women taking immunosuppressive agents. Only about 25 to 30 reports of breast-feeding have been documented, none with any known adverse effects. The decision to breast-feed must be an individual one, informing the woman that effects on the baby remain largely unknown but that breast-feeding may have considerable advantages, particularly in premature and growth-restricted babies.

Recommendations for management of pregnancy in women with a renal transplant are summarized in Figure 43.9.

Outcomes of pregnancies fathered by male transplant recipients showed that mean gestational age and mean birth weight were similar to those of the general population.

PREGNANCY IN THE RENAL DONOR

Whereas it remains true that being a renal donor does not adversely affect future pregnancy outcomes in terms of fetal birth weight, stillbirth, or prematurity, studies suggest that there may be an increased risk of preeclampsia in these women in pregnancies after organ donation than before.³⁵ The key message is that all such women should be treated as “at-risk” pregnancies and have a higher number of clinical reviews, focusing on maternal BP and urinalysis and fetal growth, than in normal low-risk pregnancies.

COURSE OF CHRONIC KIDNEY DISEASE AFTER PREGNANCY

In a review of 49 women with stages 3 to 5 CKD before conception and whose pregnancy proceeded beyond 20 weeks, GFR was lower after pregnancy than before conception, and this fall was predicted by the combination of preconception GFR below 40 ml/min and proteinuria of more than 1 g/day, but not by GFR alone.¹

The course of renal disease postpartum is unpredictable. Even some women with stable renal function throughout their pregnancy develop an acute deterioration postpartum.³⁶ Of women with moderate renal impairment (serum creatinine >1.5 mg/dl [130 μmol/l]), 50% have a significant rise in serum creatinine in the third trimester or early postpartum, and if this occurs, almost one in five progresses to end-stage renal disease within 6 months after delivery.³³

Fetal Risks in Renal Transplant Pregnancies
• Spontaneous miscarriage of about 1 in 5 to 10 cases
• Prematurity in almost half of cases
• Fetal growth restriction in almost half of cases
• Birth defects, probably no more common than in the general population
• Long-term consequences of prematurity, although most babies have normal postnatal growth and development

Figure 43.8 Fetal risks in renal transplant pregnancies. Data derived from studies of women with pre-pregnancy serum creatinine concentration in the range 1.1-1.6 mg/dl (100-140 μmol/l); some studies reported patients with higher pre-pregnancy creatinine levels.³²

General Management of Renal Transplants During Pregnancy

Pre-Pregnancy

- Graft function should be stable, with at least a one year interval from the time of transplantation.
- Discuss potential risks with transplant recipient and her partner. Although pregnancy outcomes are generally favorable, this is not always the case, and the impact of fetal death or graft loss is enormous.
- Best pregnancy outcome will occur if:
 1. Pre-pregnancy serum creatinine is less than 1.4 mg/dl (125 μ mol/l).
 2. Proteinuria is less than 500 mg/day.
 3. Blood pressure is below 140/190 mmHg.
 4. Aspirin (75-150 mg) is used if serum creatinine > 1.5 mg/dl (130 μ mol/l).
- Explain that it is sometimes prudent to delay pregnancy while using ACE inhibitors to control blood pressure and to reduce proteinuria, then switch to other drugs that are safe to use for treatment of hypertension during pregnancy, such as oxprenolol, methyldopa, or prazosin.
- Ensure that urinary tract infections are eradicated before pregnancy; prophylactic antibiotics are indicated for women who have had recurrent urine infections since their transplant to prevent pregnancy complications, such as spontaneous rupture of membranes and allograft dysfunction.
- Cyclosporine or tacrolimus blood levels should be stable.
- Diabetes should be tested for and controlled in advance of a pregnancy.

During Pregnancy

- The pregnant woman should be seen alternately between her nephrologist and obstetrician so that 2 week visits are undertaken up until 24 weeks of gestation (i.e., the time of fetal viability), and thereafter weekly visits.
- Assess fetal growth by ultrasound at least every 4 weeks, and possible more often, from 24 weeks, gestation.
- Do not adjust CNI dose during pregnancy unless there are extreme variations from stable pre-pregnancy levels.
- Screen for gestational diabetes at 28 weeks of gestation with 1-hour 50 g glucose challenge test.
- At each visit, assess BP (aim 110–140/80–90 mm Hg), proteinuria (dipstick, then PC ratio if result is dipstick result is positive), urine culture (if history of recurrent UTI, otherwise at 24, 28, and 32 weeks of gestation), electrolytes, creatinine and full blood count, CNI level, fetal growth.
- Reassess at each visit whether there is an impending indication for delivery (see fig. 43.5).

During Delivery

- Vaginal delivery is usually possible despite pelvic kidney.
- Prophylactic antibiotics are not required routinely.

Postpartum

- Monitor CNI and creatinine levels daily in hospital.
- Breast-feeding appears safe with CNI drugs, azathioprine, and corticosteroids, but discuss individual case with neonatologist.

Figure 43.9 General management of renal transplants during pregnancy. ACE, angiotensin-converting enzyme; BP, blood pressure; CNI, calcineurin inhibitor; PC ratio, protein-creatinine ratio; UTI, urinary tract infection.

Managing Women with Preexisting Renal Disease During Pregnancy

1. Women with CKD should be managed by a team comprising obstetrician, renal or obstetric medicine physician, and experienced midwife, preferably in a high-risk pregnancy clinic or day assessment unit.
2. GFR should be measured by serum creatinine in pregnancy, proteinuria as changes in spot urine protein to creatinine ratio after calculation of the initial ratio on a 24-hour urine collection, and blood pressure by sphygmomanometry or else a validated automated blood pressure recorder.
3. Women with CKD should receive low-dose aspirin for the prevention of preeclampsia or perinatal death if there is no obvious contraindication and should receive subcutaneous heparin if nephrotic syndrome develops.
4. The main determinants of a successful pregnancy outcome are the pre-pregnancy degree of proteinuria and GFR. This should be the focus in counseling women about their pregnancy risks.
5. The primary issues during pregnancy are control of maternal hypertension, regular assessment of GFR, watching for features of emerging preeclampsia, and regular assessment of fetal well-being. All of this allows optimal timing of delivery.

Figure 43.10 Managing women with preexisting renal disease during pregnancy. CKD, chronic kidney disease; GFR, glomerular filtration rate.

Surveillance by the nephrologist therefore needs be just as diligent in the first 3 months postpartum as during pregnancy. ACE inhibitors or ARB should be commenced soon after delivery for their antiproteinuric effect if GFR is stable.

SUMMARY

There are a number of factors to be considered in managing a pregnant woman with renal disease (Fig 43.10). Attention to these issues from preconception to postpartum can result in good pregnancy outcomes with preservation of maternal health.

Autosomal Dominant Polycystic Kidney Disease

Vicente E. Torres, Peter C. Harris

DEFINITION

Autosomal dominant polycystic kidney disease (ADPKD) is a multisystem disorder characterized by multiple, bilateral renal cysts associated with cysts in other organs, such as liver, pancreas, and arachnoid membranes.^{1,2} It is a genetic disorder mediated primarily by mutations in two different genes and is expressed in an autosomal dominant pattern, with variable expression. Although benign renal cysts are common, multiple bilateral cysts are not. Therefore, an underlying inherited disease should be considered in patients with normal renal function and multiple bilateral renal cysts.

ETIOLOGY AND PATHOGENESIS

The polycystic kidney disease (PKD) proteins now known as polycystin 1 and polycystin 2 play a critical role in the normal function of the primary cilium that is essential to maintaining the differentiated phenotype of tubular epithelium. Disordered function of polycystins is the basis for cyst formation in PKD by permitting a less differentiated tubular epithelial phenotype.

Genetic Mechanisms

ADPKD is genetically heterogeneous with two genes identified (Fig. 44.1), *PKD1* (chromosome 16p13.3) and *PKD2* (4q21). Autosomal dominant polycystic liver disease (ADPLD) also exists as an independent entity and is genetically heterogeneous; the first two genes identified (*PRKCSH* in chromosome 19 and *SEC63* in chromosome 6) account for about one third of isolated ADPLD cases.

Evidence from animal models of ADPKD and analysis of cystic epithelia have shown that renal cysts may develop from loss of functional polycystin with somatic inactivation of the normal allele, which is consistent with a “two-hit” mechanism. However, cysts can develop even if the protein is not completely lost. Furthermore, transgenic rodents overexpressing either *Pkd1* or *Pkd2* develop renal cystic disease resembling human ADPKD, which suggests that multiple genetic mechanisms that cause an imbalance in the expression of polycystins can affect their function and lead to development of cysts.²

Polycystic Kidney Disease Proteins

Polycystin 1 (PC1) and polycystin 2 (PC2) belong to a subfamily of transient receptor potential (TRP) channels.

PC1 (TRPP1; ~460 kd) has the structure of a receptor or adhesion molecule and contains a large extracellular N region,

11 transmembrane regions, and a short intracellular C region (see Fig. 44.1). It interacts with PC2 through a coiled-coil domain in the C-terminal portion and with multiple other proteins at different extracellular and intracellular sites. PC1 is found in the primary cilia, cytoplasmic vesicles, plasma membrane at focal adhesions, desmosomes, adherens junctions, and possibly endoplasmic reticulum and nuclei. PC1 may regulate the mechanical strength of adhesion between cells by controlling the formation of stabilized, actin-associated adherens junctions.³

PC2 (TRPP2; ~110 kd) contains a short N-terminal cytoplasmic region with a ciliary targeting motif, six transmembrane domains, and a short C-terminal portion. PC2 is localized predominantly to the endoplasmic reticulum but also to the plasma membrane, primary cilium, centrosome, and mitotic spindles in dividing cells.

Mechanisms of Cyst Formation

Experimental data indicate that the timing of ciliary loss or *Pkd1* inactivation determines the rate of development of cystic disease. Early inactivation results in rapidly progressive cystic disease.⁴ Cysts also develop rapidly in the corticomedullary region (pars recta and thick ascending limbs of Henle) of adult mouse kidneys subjected to renal ischemia or reperfusion injury to stimulate cell proliferation.⁵ Analysis of pre-cystic tubules shows that the loss of cilia results in aberrant planar cell polarity manifested by abnormalities in the orientation of cell division. The age dependence, location, and induction of the cysts by ischemia or reperfusion injury suggest that cyst formation is associated with increased rates of cell proliferation.

The polycystins are involved in the detection of extracellular cues at primary cilia, cell-cell contacts, and cell-matrix contacts and are essential to maintain the differentiated phenotype of the tubular epithelium. Reduction in one of the polycystins below a critical threshold results in a phenotypic switch characterized by inability to maintain planar polarity, increased rates of proliferation and apoptosis, expression of a secretory phenotype, and remodeling of the extracellular matrix. The molecular mechanisms include alterations of intracellular calcium homeostasis and activation of cyclic nucleotide, tyrosine kinase receptor, canonical Wnt, and other intracellular signaling pathways (Fig. 44.2).²

Beyond the loop of Henle, tubular epithelial cells have the capacity to secrete as well as to reabsorb solutes and fluid. Normally, absorptive flux exceeds secretory flux. Sodium chloride reabsorption in cortical collecting duct principal cells, arguably the main origin of the cysts in ADPKD, is driven by

Figure 44.1 Polycystins: genes, mRNAs, and proteins. Diagrammatic representation of chromosome 16 (left) and chromosome 4 (right). Intron-exon sequences of *PKD1* (upper left) and *PKD2* (upper right). Diagram of proposed structural features of the polycystin 1 and polycystin 2 proteins (center).

low intracellular sodium concentration generated by basolateral Na^+, K^+ -ATPase. Sodium chloride enters the luminal membrane through epithelial sodium and chloride channels. Apical recycling of potassium occurs through renal outer medullary K (ROMK) channels. Water enters the cells across the luminal membrane through vasopressin-sensitive aquaporin 2 channels. Cystic epithelial cells are markedly different from normal cortical collecting duct principal cells. Chloride enters across basolateral $\text{Na}^+ - \text{K}^+ - 2\text{Cl}^-$ cotransporters, driven by the sodium gradient generated by basolateral Na^+, K^+ -ATPase, and exits across apical protein kinase A-stimulated cystic fibrosis transmembrane conductance regulator (CFTR). Basolateral recycling of potassium may occur through KCa3.1 .^{2,6}

In tubular epithelial cells, the primary cilium projects into the lumen and is thought to have a sensory role. The PC1-PC2 complex acts as a sensor on cilia that translates mechanical or chemical stimulation into calcium influx through PC2 channels. This in turn induces calcium release from intracellular stores.

A common finding in animal models of PKD is increased levels of cyclic adenosine monophosphate (cAMP), not only in the kidney but also in the liver, vascular smooth muscle, and choroid plexus. It has been suggested that alterations in intracellular calcium homeostasis account for the accumulation of cAMP, which in turn contributes to the development and progression of PKD by stimulating CFTR-driven chloride and fluid secretion and cell proliferation. Whereas cAMP inhibits MAP kinase signaling and cell proliferation under normal conditions, it stimulates cell proliferation in PKD or in conditions of calcium

deprivation, probably linked to the alterations in intracellular calcium. Cell proliferation may be further enhanced by stimulation of epidermal growth factor-like factors present in cyst fluid, increased insulin-like growth factor 1 in cystic tissues, and activation of mTOR.

Upregulation of the vasopressin V_2 receptor and high circulating vasopressin levels may contribute to the increased cAMP levels.

Liver Cyst Development

Liver cysts arise by excessive proliferation and dilation of biliary ductules and peribiliary glands. Scanning electron microscopy has shown that the cyst epithelium displays heterogeneous features, being normal in small cysts (<1 cm), characterized by rare or shortened cilia in 1- to 3-cm cysts, and exhibiting absence of both primary cilia and microvilli in large cysts (>3 cm).⁷ Estrogen receptors, insulin-like growth factor 1 (IGF1), IGF1 receptors, and growth hormone receptor are expressed in the epithelium lining the hepatic cysts, and estrogens and IGF1 stimulate hepatic cyst-derived cell proliferation.⁷ Cyst growth is also promoted by growth factors and cytokines secreted into the cyst fluid.

Hypertension

Hypertension is a major clinical manifestation and predictor of outcome in ADPKD (see [Clinical Manifestations](#)). Several factors contribute to the development of hypertension in

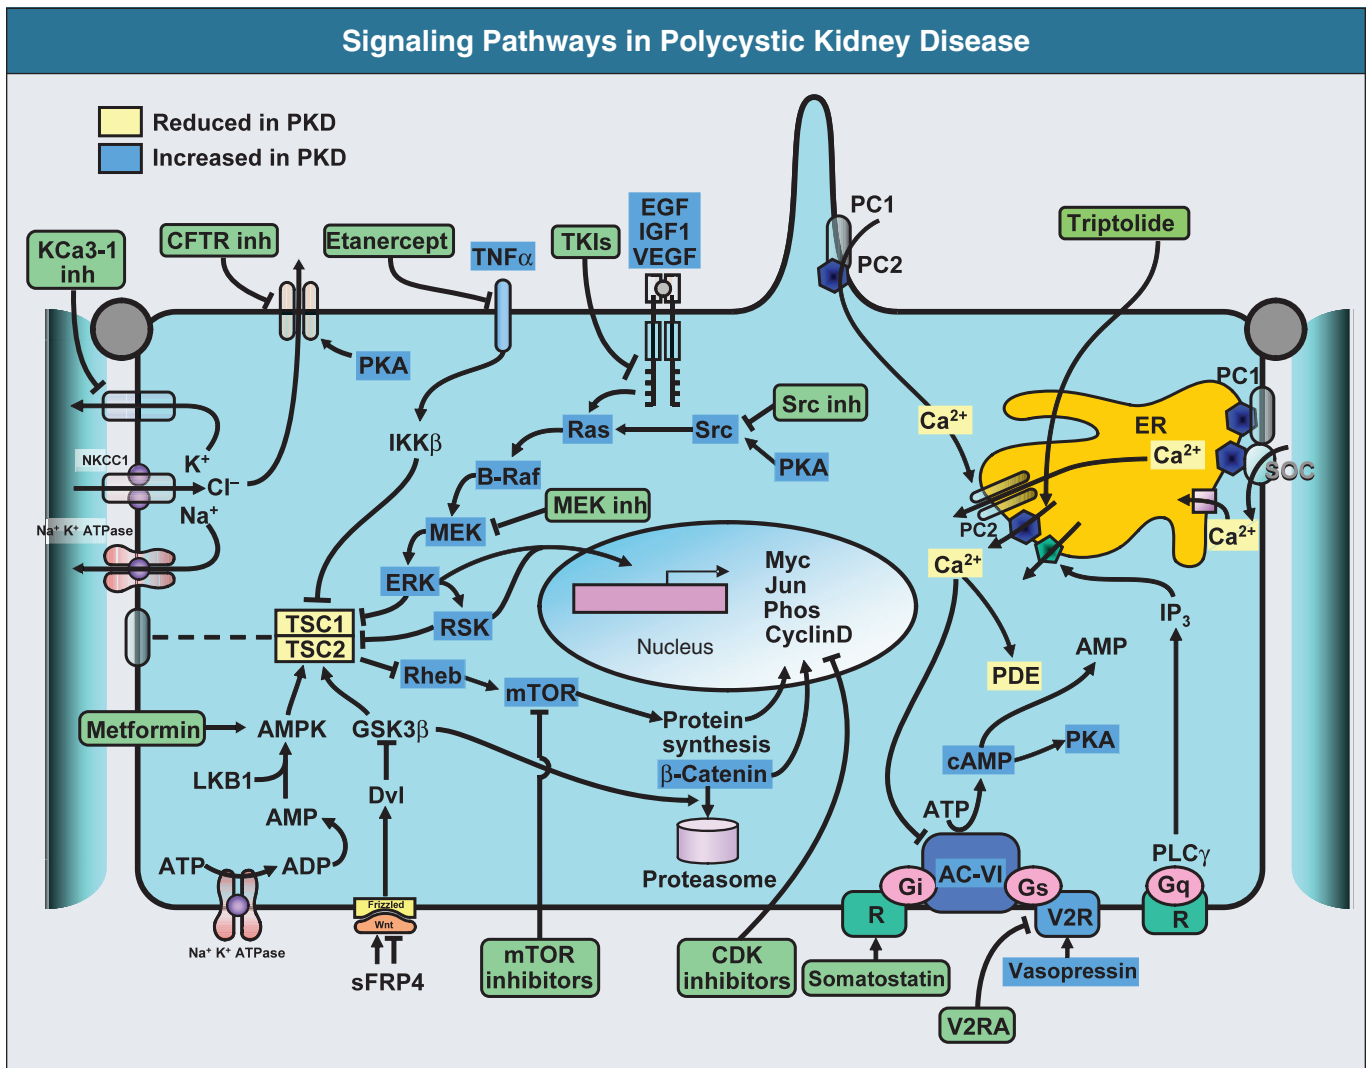

Figure 44.2 Signaling pathways in polycystic kidney disease. Pathways that are upregulated or downregulated in polycystic kidney disease and rationale for potential therapies (green boxes).

Dysregulation of intracellular cAMP, mislocalization of ErbB receptors, and upregulation of epidermal growth factor (EGF), insulin-like growth factor 1 (IGF1), vascular endothelial growth factor (VEGF), and tumor necrosis factor α (TNF α) occur in cells and kidneys bearing PKD mutations.

Increased accumulation of cAMP in polycystic kidneys may result from (1) disruption of the polycystin complex because PC1 may act as a G_i protein-coupled receptor; (2) stimulation of calcium inhibitable AC-VI or inhibition of calcium-dependent PDE1 by a reduction in intracellular calcium; (3) increased circulating vasopressin due to an intrinsic concentrating defect; and (4) upregulation of vasopressin V₂ receptors. Increased cAMP levels contribute to cystogenesis by stimulating chloride and fluid secretion. In addition, cAMP stimulates mitogen-activated protein kinase/extracellularly regulated kinase (MAPK/ERK) signaling and cell proliferation in a Src- and Ras-dependent manner in cyst-derived cells or in wild-type tubular epithelial cells treated with calcium channel blockers or in a low Ca²⁺ medium. Activation of tyrosine kinase receptors by ligands present in cystic fluid also contributes to the stimulation of MAPK/ERK signaling and cell proliferation. Phosphorylation of tuberin by ERK (or inadequate targeting to the plasma membrane due to defective interaction with polycystin 1) may lead to the dissociation of tuberin and hamartin and the activation of Rheb and mTOR. Upregulation of TNF α or downregulation of AMPK signaling may also stimulate mTOR signaling through inhibition of the tuberin-hamartin complex. Activation of MAPK may also blunt cystogenesis through inhibition of CFTR and ERK. Upregulation of Wnt signaling stimulates mTOR and β -catenin signaling. ERK and mTOR activation promotes G₁/S transition and cell proliferation through regulation of cyclin D1, phosphorylation of retinoblastoma protein (RB) by CDK4/6–cyclin D and CDK2–cyclin E, and release of E2F transcription factor.

ADPKD. Activation of the intrarenal renin-angiotensin system (RAS) may play an important role, but there is controversy whether the circulating RAS is inappropriately activated.⁸ PC1 and PC2 are expressed in vascular smooth muscle and endothelium, along with enhanced vascular smooth muscle contractility⁹ and impaired endothelium-dependent vasorelaxation, suggesting that disruption of polycystin function contributes to hypertension. PC1 in the primary cilia plays a role in the translation of

physiologic changes in fluid shear stress into cytosolic calcium and nitric oxide signals. Other factors include increased sympathetic nerve activity and plasma endothelin 1 levels and insulin resistance.

Endothelial vasodilation and constitutive nitric oxide synthase activity are reduced in subcutaneous resistance vessels from patients with ADPKD and normal glomerular filtration rate (GFR). Flow-induced vasodilation of the brachial artery is

inconsistently impaired,^{10,11} whereas pulse wave reflection is amplified, suggesting a predominant involvement of small resistance vessels.¹² Reduced coronary flow velocity reserve and increased carotid intima-media thickness in normotensive patients with normal GFR suggest that atherosclerosis starts early in the course of ADPKD.¹³

Reduced nitric oxide endothelium-dependent vasorelaxation in ADPKD may be due to increased plasma levels of asymmetric dimethylarginine, a mechanism common to all hypertension associated with kidney disease (for further discussion, see Chapter 78).

EPIDEMIOLOGY

ADPKD occurs worldwide and in all races, with a prevalence estimated to be between 1:400 and 1:1000.¹ Approximately 2100 ADPKD patients start renal replacement therapy yearly in the United States. The percentage of end-stage renal disease (ESRD) due to ADPKD is less among African Americans than among Caucasians because of a higher incidence of other causes of ESRD. Yearly incidence rates for ESRD caused by ADPKD are 8.7 and 6.9 per million (1998–2001, United States), 7.8 and 6.0 per million (1998–1999, Europe), and 5.6 and 4.0 (1999–2000, Japan) in men and women, respectively. Age-adjusted sex ratios greater than unity (1.2–1.3) suggest more progressive disease in men than in women. Consistent with this, a survival analysis of 1391 parent-offspring pairs showed a significant male gender effect (HR, 1.424; 95% CI, 1.180 to 1.719) on age at ESRD (58 and 57 years for female parents and offspring and 54 and 54 years for male parents and offspring), but no difference between pairs.¹⁴

PHENOTYPIC VARIABILITY

Genic, allelic, and gene modifier effects contribute to the high phenotypic variability of ADPKD. *PKD1*-associated disease is more severe than *PKD2*-associated disease (age at ESRD, 54 years versus 74 years for *PKD1* and *PKD2*, respectively). The greater severity of *PKD1* is due to the development of more cysts at an early age, not to faster cyst growth.¹⁵ Both *PKD1* and *PKD2* can be associated with severe polycystic liver disease and vascular abnormalities. Because of the lesser severity of the renal involvement, the prevalence of *PKD2*-associated disease has likely been underestimated in clinical studies.

PKD1 and *PKD2* mutations are highly variable and usually private (unique to a kindred). The ADPKD Mutation Database (<http://pkdb.mayo.edu>) lists 333 truncating *PKD1* mutations identified in 417 families with a total of 869 variants including missense mutations and silent polymorphisms. Ninety-five *PKD2* truncating mutations are listed in 178 families, with a total of 128 different variants.

The influence of allelic factors (mutation type or location) on the severity of ADPKD is limited. Patients with mutations in the 5' region of *PKD1* have more severe disease (19% versus 40% with adequate renal function at 60 years) and are more likely to have intracranial aneurysms and aneurysm ruptures than are patients with 3' mutations. There are no clear correlations with mutation type in *PKD1* or *PKD2* or with mutation type or position in *PKD2*. Recently, however, hypomorphic or incompletely penetrant *PKD1* or *PKD2* alleles have been described.¹⁶ These alleles alone may result in mild cystic disease; two such alleles cause typical to severe disease and in combination with an inactivating allele may be associated with early-onset disease.

The large intrafamilial variability of ADPKD highlights a role for genetic background in disease presentation. Age at clinical manifestations in ADPKD is less variable within than between families, which suggests a common familial modifying background for early and severe disease expression (e.g., mutations or variants in genes encoding other cystoproteins). The contiguous deletion of the adjacent *PKD1* and *TSC2* is characterized by childhood PKD with additional clinical signs of tuberous sclerosis complex. Other modifying loci are likely to account for more common and subtle intrafamilial variability, but studies of candidate loci, selected because of presumed relevance to the pathogenesis of ADPKD or association with prognosis in other renal diseases, have been mostly disappointing.

DIAGNOSIS

Only individuals who have been properly informed about the advantages and disadvantages of screening should be offered presymptomatic screening. If ADPKD is diagnosed, the patient can receive appropriate genetic counseling, and risk factors such as hypertension can be identified and treated early. If ADPKD is absent, the patient can be reassured. Disadvantages of presymptomatic screening relate to insurability and employability. Presymptomatic screening of children is not recommended, but this advice can be expected to change when more effective therapy for the disease becomes available.

Renal Ultrasound

Renal ultrasound is commonly used for presymptomatic testing because of cost and safety. Revised criteria have been proposed to improve the diagnostic performance of ultrasound in ADPKD (Fig. 44.3). At least three (unilateral or bilateral) renal cysts and two cysts in each kidney are sufficient for diagnosis of at-risk individuals aged 15 to 39 and 40 to 59 years, respectively.¹⁷ Three or more (unilateral or bilateral) cysts have a positive predictive

Ultrasound Criteria for the Diagnosis of ADPKD				
Age (years)	Criteria	PPV	NPV	
Original Ravine's PKD1 diagnostic criteria				
15–29	≥2 cysts, unilateral or bilateral	99.2	87.7	
30–39	≥2 cysts in each kidney	100	87.5	
40–59	≥2 cysts in each kidney	100	94.8	
≥60	≥4 cysts in each kidney	100	100	
Revised unified diagnostic criteria				
15–29	≥3 cysts, unilateral or bilateral	100	85.5	
30–39	≥3 cysts, unilateral or bilateral	100	86.4	
40–59	≥2 cysts in each kidney	100	94.8	
≥60	≥4 cysts in each kidney	100	100	
Revised criteria for exclusion of diagnosis				
15–29	≥1 cyst	96.6	90.8	
30–39	≥1 cyst	94.0	98.3	
40–59	≥2 cysts	96.7	100	
≥60	≥3 cysts in each kidney	100	100	

Figure 44.3 Ultrasound criteria for diagnosis of ADPKD. NPV, negative predictive value; PPV, positive predictive value. (Reprinted with permission from reference 33.)

value of 100% in the younger age group and minimize false-positive diagnoses because 2.1% and 0.7% of the genetically unaffected individuals younger than 30 years have one and two renal cysts, respectively. For at-risk individuals 60 years of age and older, four or more cysts in each kidney are required.

Whereas the overall specificity and positive predictive value of ultrasound are high by use of these criteria, their sensitivity and negative predictive value when applied to 15- to 59-year-old *PKD2* patients are low. This is a problem in the evaluation of potential kidney donors, in which exclusion of the diagnosis is important.¹⁷ Different criteria have therefore been proposed to exclude a diagnosis of ADPKD in an individual at risk from a family with an unknown genotype. An ultrasound scan finding of normal kidneys or one renal cyst in an individual aged 40 years or older has a negative predictive value of 100%. The absence of any renal cyst provides near certainty that ADPKD is absent in at-risk individuals aged 30 to 39 years, with a false-negative rate of 0.7% and a negative predictive value of 98.7%. A normal or indeterminate ultrasound scan does not exclude ADPKD with certainty in an at-risk individual younger than 30 years; a normal magnetic resonance (MR) or contrast-enhanced computed tomography (CT) scan provides further assurance, but there are insufficient data to quantify its predictive accuracy.

Genetic Testing

Genetic testing can be performed when a precise diagnosis is needed and the results of imaging testing are indeterminate. However, there are limitations to genetic testing, by either linkage or mutation analysis. Linkage analysis requires accurate diagnosis and the availability and willingness of sufficient affected family members to be tested; it is feasible in less than 50% of families. *De novo* mutations can also complicate interpretation of results. Molecular testing by direct DNA sequencing is now possible in ~85% of patients.¹⁸ However, as most mutations are unique and up to one third of *PKD1* changes are missense, the pathogenicity of some changes is difficult to prove.

In preimplantation genetic diagnosis, genetic analysis is carried out on single blastomeres from preimplantation embryo biopsy specimens obtained after in vitro fertilization, and only embryos unaffected by the disease under investigation are selected for transfer. Preimplantation genetic diagnosis for ADPKD has been performed in very few cases; it is complicated by the genetic heterogeneity of the disease and by the large size and complex structure of the *PKD1* gene.

DIFFERENTIAL DIAGNOSIS

Renal cystic disease can be a manifestation of many other systemic diseases. Conditions to keep in mind when renal cystic disease is detected but the presentation is not typical of ADPKD include autosomal recessive PKD, tuberous sclerosis complex, von Hippel–Lindau disease, and orofacioidigital syndrome type I as well as medullary sponge kidney and simple renal cysts. These are discussed further, including differential diagnosis, in Chapter 45. If the patient has ESRD, acquired cystic disease should also be considered (see Chapter 85).

CLINICAL MANIFESTATIONS

ADPKD is a multisystem disorder. Multiple renal and extrarenal manifestations of ADPKD have been described that cause significant complications.

Renal manifestations of ADPKD
Functional Manifestations
Concentrating defect
Reduced urine NH ₄ relative to pH
Reduced renal blood flow
Hypertension → Target Organ Damage
Cardiac
Cerebrovascular
Arteriosclerosis and glomerulosclerosis
Peripheral vascular disease
Pain, Caused by
Cyst hemorrhage
Gross hematuria
Nephrolithiasis
Infection
Renal enlargement
Renal Failure, Possibly Due to
Interstitial inflammation
Apoptosis of tubular epithelial cells
Hypertensive glomerulosclerosis
Compression atrophy

Figure 44.4 Renal manifestations of ADPKD.

Renal Manifestations

A number of clinical features that result from renal damage can be identified (Fig. 44.4). Reduction in urinary concentrating capacity and glomerular hyperfiltration are early functional abnormalities that can be observed in some children and adolescents with ADPKD.

Renal Size

Renal size increases with age, and renal enlargement eventually occurs in 100% of patients with ADPKD. The severity of structural abnormality correlates with the manifestations of ADPKD, such as pain, hematuria, hypertension, and renal impairment.¹⁹ Massive renal enlargement can lead to compression of local structures, resulting in such complications as inferior vena cava compression and digestive symptoms. Most manifestations are directly related to the development and enlargement of renal cysts. The Consortium for Radiologic Imaging Studies of Polycystic Kidney Disease (CRISP), a prospective study of 241 patients by annual magnetic resonance imaging (MRI), has shown that total kidney volume and cyst volumes increased exponentially.¹⁹ Rates of growth were relatively constant, averaging 5.3% per year, but highly variable from patient to patient. Baseline total kidney volume predicted the subsequent rate of increase in renal volume and was associated with declining GFR in patients with baseline total kidney volume above 1500 ml.

Pain

Episodes of acute renal pain are seen frequently; causes include cyst hemorrhage, infection, stone, and rarely tumor, and these must be investigated thoroughly. A few ADPKD patients

with renal enlargement and structural distortion develop chronic flank pain without specifically identifiable etiology.

Hematuria and Cyst Hemorrhage

Visible hematuria may be the initial presenting symptom and occurs in up to 40% of ADPKD patients at some time during the course of the disease. Many have recurrent episodes. Differential diagnosis includes cyst hemorrhage, stone, infection, and tumor. Cyst hemorrhage is a frequent complication and produces gross hematuria when the cyst communicates with the collecting system. Frequently, the cyst does not communicate with the collecting system, and flank pain without hematuria occurs. It can present with fever, raising the possibility of cyst infection. On occasion, a hemorrhagic cyst will rupture, resulting in a retroperitoneal bleed that can be significant, potentially requiring transfusion. In most patients, cyst hemorrhage is self-limited, resolving within 2 to 7 days. If symptoms of hematuria or flank pain last longer than 1 week or if the initial episode of hematuria occurs after the age of 50 years, investigation to exclude neoplasm should be undertaken.

Urinary Tract Infection and Cyst Infection

Urinary tract infection is common in ADPKD, but its incidence may have been overestimated because sterile pyuria is common in these patients. Urinary tract infection presents as cystitis, acute pyelonephritis, cyst infection, and perinephric abscesses. As in the general population, females are affected more frequently than males. Most infections are caused by *Escherichia coli*, *Klebsiella* species, *Proteus* species, and other Enterobacteriaceae. The route of infection in acute pyelonephritis and cyst infection is usually retrograde from the bladder; therefore, cystitis should be promptly treated to prevent complicated infections.

CT and MRI are both sensitive to detect complicated cysts and to provide anatomic definition, but the findings are not specific for infection. Nuclear imaging, especially indium-labeled white blood cell scanning, is useful, but both false-negative and false-positive results are possible. [^{18}F]Fluorodeoxyglucose (FDG) positron emission tomography (PET) has recently been used for detection of infected cysts.²⁰ FDG is taken up by inflammatory cells because of their high metabolic rate but is filtered by the kidneys, not reabsorbed, and appears in the collecting system, which may limit its use in diagnosis of renal cyst infections; its present role is for diagnosis of infected liver cysts. FDG PET is expensive and not yet widely available, but it provides rapid imaging with high spatial resolution, high target to background ratio, low radiation burden, and high interobserver agreement.

When there is fever and flank pain with suggestive diagnostic imaging but blood and urine cultures are negative, cyst aspiration under ultrasound or CT guidance should be undertaken to culture the organism and to assist in selection of antimicrobial therapy.

Nephrolithiasis

Renal stone disease occurs in about 20% of patients with ADPKD. Most stones are composed of uric acid, calcium oxalate, or both. Uric acid stones are more common in ADPKD than in stone formers without ADPKD. Urinary stasis secondary to distorted renal anatomy possibly plays a role in the pathogenesis of nephrolithiasis. Predisposing metabolic factors include decreased ammonia excretion, low urinary pH, and low urinary citrate concentration.²¹

Stones can be difficult to diagnose on imaging in ADPKD because of cyst wall and parenchymal calcification. The distorted anatomy can cause difficulty in localizing stones to the collecting system on plain films. Intravenous urography has the advantage of specifically localizing stone material to the collecting system and may provide clues to stone composition. Intravenous urography can also detect pericalyceal tubular ectasia, found in 15% of ADPKD patients. CT scanning is more sensitive in detecting small or radiolucent stones and for differentiating stones from tumor, clot, and cyst wall or parenchymal calcification. Dual-energy CT is increasingly used to distinguish between calcium and uric acid stones.

Hypertension

Hypertension is the most common manifestation of ADPKD and a major contributor to renal disease progression (Fig. 44.5) and cardiovascular morbidity and mortality. Microalbuminuria, proteinuria, and hematuria, which are independent risk factors for renal functional decline, are more common in hypertensive patients with ADPKD. Hypertension may also increase morbidity from valvular heart disease and intracranial aneurysms, which are common in ADPKD.

Ambulatory blood pressure monitoring of children or young adults without diagnosed hypertension often reveals elevated blood pressure, attenuated nocturnal blood pressure dipping, and exaggerated blood pressure response during exercise. A study stratified 65 children by blood pressure into three cohorts: hypertensive (≥ 95 th percentile), borderline hypertensive (75th to 95th percentile), and normotensive (≤ 75 th percentile).²² Both the hypertensive and borderline hypertensive children had significantly higher left ventricular mass indices than normotensive children did. Among normotensive children, indices were significantly higher in those within the upper quartile of the normal blood pressure. These observations suggest that target organ damage develops early in ADPKD and that antihypertensive treatment may be indicated in children with ADPKD and borderline hypertension.

End-Stage Renal Disease

In most patients, renal function is maintained within the normal range, despite relentless growth of cysts, until the fourth to sixth

Figure 44.5 Patients with polycystic kidney disease and hypertension at diagnosis have less probability of renal survival than those with normal blood pressure. (Reprinted with permission from reference 47.)

decade of life. By the time renal function starts declining, the kidneys usually are markedly enlarged and distorted with little recognizable parenchyma on imaging studies. At this stage, the average rate of GFR decline is 4.4 to 5.9 ml/min per year. Nevertheless, ESRD is not inevitable in ADPKD. Up to 77% of patients are alive with preserved renal function at age 50 years, and 52% at age 73 years. Men tend to progress to renal failure more rapidly and require renal replacement therapy at a younger age than do women. Other risk factors for renal failure include black race, diagnosis of ADPKD before the age of 30 years, first episode of hematuria before the age of 30 years, onset of hypertension before the age of 35 years, hyperlipidemia, low high-density lipoprotein cholesterol level, and sickle cell trait.²³

Several mechanisms account for renal function decline. The CRISP study has confirmed that kidney and cyst volumes are the strongest predictors of renal functional decline.¹⁹ CRISP also found that renal blood flow (or vascular resistance) is an independent predictor.²⁴ This points to the importance of vascular remodeling in the progression of the disease and may account for cases in which the decline of renal function seems to be out of proportion to the severity of the cystic disease. Other factors, such as heavy use of analgesics, may contribute to chronic kidney disease progression in some patients.

Extrarenal Manifestations

Polycystic Liver Disease

Polycystic liver disease (PLD) is the most common extrarenal manifestation of ADPKD. It is associated with both *PKD1* and *PKD2* genotypes. In addition, PLD also occurs as a genetically distinct disease in the absence of renal cysts. Most simple hepatic cysts are solitary, and PLD should be suspected when four or more cysts are present in the hepatic parenchyma. The liver in PLD contains multiple microscopic or macroscopic cysts that result in hepatomegaly (Fig. 44.6), but typically there is preservation of normal hepatic parenchyma and liver function.

Hepatic cysts are exceedingly rare in children with ADPKD. Their frequency increases with age and may have been underestimated by ultrasound and CT studies. Their prevalence by MRI scanning in the CRISP study is 58%, 85%, and 94% in 15- to 24-year-old, 25- to 34-year-old, and 35- to 46-year-old participants.²⁵ Women develop more cysts, at an earlier age than men do. Women who have multiple pregnancies or who have used oral contraceptive agents or estrogen replacement therapy postmenopausally have worse disease, supporting the importance of estrogen exposure in hepatic cyst growth.

Typically, PLD is asymptomatic, but reported symptoms have become more frequent as the life span of ADPKD patients is prolonged with dialysis and transplantation. Symptoms result from mass effect or from complications related to the cysts themselves. Symptoms typically caused by massive enlargement of the liver or by mass effect from a single or a limited number of dominant cysts include dyspnea, orthopnea, early satiety, gastroesophageal reflux, mechanical low back pain, uterine prolapse, and even rib fracture. Other complications caused directly by mass effect include hepatic venous outflow obstruction, inferior vena cava compression, portal vein compression, and bile duct compression presenting as obstructive jaundice. Hepatic venous outflow obstruction is an uncommon condition caused by severe extrinsic compression of the intrahepatic inferior vena cava and hepatic veins by cysts, rarely with superimposed thrombosis. Symptomatic cyst complications include cyst hemorrhage, which occurs less frequently than renal cyst hemorrhage; cyst infection; and the rare occurrence of torsion or rupture of cysts. Hepatic cyst infection can be a serious complication and typically presents with localized pain, fever, leukocytosis, elevated sedimentation rate, and often elevated alkaline phosphatase. Enterobacteriaceae are the most common microorganisms causing cyst infection. The same imaging techniques discussed for the investigation of renal cyst infections may be useful for the localization of infected cysts in the liver.

Intracranial Aneurysms

Intracranial aneurysms occur in about 8% of those with ADPKD. There is some familial clustering; intracranial aneurysms occur in 6% of patients with a negative family history and 16% of those with a positive family history.²⁶ Most are asymptomatic. Focal findings, such as cranial nerve palsy and seizure, may result from compression of local structures by an enlarging aneurysm (Fig. 44.7). Yearly rupture rates increase with size, ranging from less than 0.5% for aneurysms smaller than 5 mm in diameter to 4% for aneurysms larger than 10 mm in diameter. Rupture carries a 35% to 55% risk for combined severe morbidity and mortality. The mean age at rupture in ADPKD is 39 years (compared with 51 years in the general population), with a range of 15 to 69 years. Most patients have normal renal function, and up to 29% have normal blood pressure at the time of rupture.

Screening is not indicated for all people with ADPKD because most intracranial aneurysms found by presymptomatic screening are small, have a low risk for rupture, and require no treatment because the risks of intervention exceed any risk of rupture.²⁷ Indications for screening in patients with a good life expectancy

Figure 44.6 Variable presentation of symptomatic polycystic liver disease. **A**, Hepatomegaly caused by a very large, isolated, dominant cyst. **B**, Hepatomegaly caused by several large cysts. **C**, Hepatomegaly caused by multiple smaller cysts throughout the hepatic parenchyma.

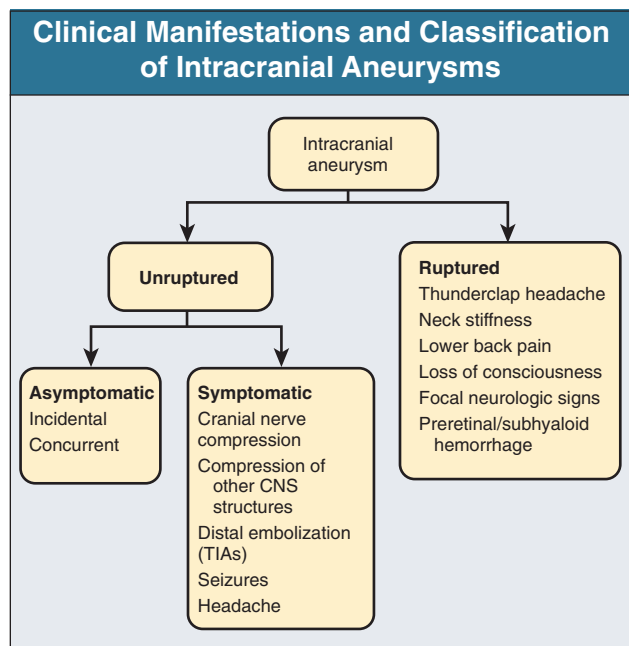

Figure 44.7 Intracranial aneurysms. Clinical manifestations and classification. CNS, central nervous system; TIAs, transient ischemic attacks.

include family history of intracranial aneurysm or subarachnoid hemorrhage, previous aneurysmal rupture, preparation for elective surgery with potential hemodynamic instability, high-risk occupations (e.g., airline pilots), and significant anxiety on the part of the patient despite adequate information about the risks. MR angiography is the diagnostic imaging modality of choice for presymptomatic screening because it is noninvasive and does not require the intravenous administration of contrast material. CT angiography is a satisfactory alternative if there is no contraindication to the intravenous administration of contrast material.

Other Vascular Abnormalities

In addition to intracranial aneurysms, ADPKD has been associated with other vascular abnormalities, such as thoracic aortic and cervicocephalic arterial dissections, coronary artery aneurysms, and retinal artery and vein occlusions (Fig. 44.8). Thoracic aortic dissection is seven times more common in ADPKD than in the general population in autopsy series, but reported cases are rare. Rare patients with coronary artery aneurysms can present with cardiac ischemia and thrombus in the aneurysm in the absence of atherosclerotic disease. Several case reports describe abdominal aortic aneurysms in ADPKD. However, a prospective ultrasound study showed neither a wider aortic diameter nor a higher prevalence of abdominal aortic aneurysms in ADPKD patients compared with unaffected kindred in any age group. On pathologic examination, tissues from arterial aneurysms and dissections demonstrate disruption of elastic tissue. Polycystin 1 and polycystin 2 are both expressed in the myocytes of elastic and large distributive arteries, suggesting a direct pathogenetic role for ADPKD-related mutations in the arterial complications of this disease.

Valvular Heart Disease and Other Cardiac Manifestations

Mitral valve prolapse is the most common valvular abnormality and has been demonstrated in up to 25% of ADPKD patients by

Figure 44.8 Vascular manifestations of ADPKD. **A**, Gross specimen demonstrating bilateral aneurysms of the middle cerebral arteries. **B**, Gross specimen demonstrating a thoracic aortic dissection extending into the abdominal aorta in a patient with ADPKD.

echocardiography. Mitral regurgitation, tricuspid regurgitation, and tricuspid prolapse also occur more frequently in ADPKD than in unaffected kindred. Aortic regurgitation may be associated with dilation of the aortic root. On histologic examination, valvular tissue shows myxoid degeneration with disruption of collagen, as seen in Marfan and Ehlers-Danlos syndromes. Although the lesions may progress with time, they rarely require valve replacement. Screening echocardiography is not indicated unless a murmur is detected on physical examination. Small, hemodynamically insignificant pericardial effusion can be detected by CT scanning in up to 35% of ADPKD patients.²⁸

Other Associated Conditions

Cyst formation has been described in such diverse organs as the pancreas, seminal vesicles, and arachnoid membrane (Fig. 44.9). Seminal vesicle cysts, usually multiple and bilateral, are found in 40% of ADPKD compared with 2% of nonaffected males. Ovarian cysts are not associated with ADPKD. Pancreas and arachnoid membrane cysts are present in 5% and 8% of patients, respectively. Pancreatic cysts are almost always asymptomatic, with very rare occurrences of recurrent pancreatitis and possibly chance associations of intraductal papillary mucinous tumor or carcinoma. Epididymal and prostate cysts may also occur with increased frequency. Sperm abnormalities with defective motility are common in ADPKD and rarely may be a cause of male infertility.²⁹ Spinal meningeal diverticula may occur with

Figure 44.9 Extrarenal manifestations of ADPKD. Arachnoid cysts (arrows) demonstrated by CT (A) and MRI (B).

increased frequency and rarely present with intracranial hypotension (orthostatic headache, diplopia, hearing loss, ataxia) due to cerebrospinal fluid leak.³⁰ The prevalence of colonic and duodenal diverticula may also be increased.³¹

PATHOLOGY

Polycystic kidneys are diffusely cystic and enlarged (Fig. 44.10). Size varies from normal to weighing more than 4 kg. The outer and cut surfaces show numerous spherical cysts of varying size, which are distributed evenly between cortex and medulla. The collecting system typically is distorted. The epithelium lining the cysts is characterized by hyperplastic changes, including flat nonpolypoid hyperplasia, polypoid hyperplasia and microscopic adenomas (Fig. 44.11), and increased rates of cell proliferation and apoptosis. Despite the frequency of hyperplastic lesions and microscopic adenomas, the incidence of renal cell carcinoma is not increased.

Cysts arise from focal dilation of existing renal tubules, arising from all segments of the nephron and collecting ducts. As they grow, they dissociate from the parent tubule and eventually become isolated, fluid-filled sacs. There is no agreement on whether the cysts originate preferentially from particular tubular segments. Cysts with fluid sodium, chloride, potassium, and urea concentrations similar to those of plasma (nongradient cysts) are thought to be derived from proximal tubules, whereas cysts with

Figure 44.10 Polycystic kidneys. Markedly enlarged polycystic kidneys from a patient with ADPKD in comparison to a normal kidney in the middle.

Figure 44.11 Renal cyst histology in ADPKD. A, Papillary hyperplasia of cyst epithelium. B, Papillary microscopic adenoma in an ADPKD kidney. (Magnification $\times 200$.)

low sodium and chloride and high potassium and urea concentrations are considered to be distally derived. Histochemical studies provide inconsistent evidence about the site of origin within the tubule. Most studies indicate that cysts are predominantly of distal nephron and collecting duct origin. Studies in advanced renal disease showing proximal tubular cysts may be confounded by the effects of obstruction and acquired renal cystic disease. A study has shown that most claudin isoforms expressed in ADPKD cysts are of distal nephron and collecting duct origin and that claudin 2, normally expressed in proximal tubules, is absent from the cysts.³²

Figure 44.12 Surgical cyst fenestration for symptomatic ADPKD. **A**, Effects on relief of pain. **B**, Rate of decline of renal function. Orange lines indicate the course of renal function in individual patients who underwent cyst fenestration at month 0. (Reprinted with permission from reference 48.)

Polycystic kidneys demonstrate advanced sclerosis of preglomerular vessels, interstitial fibrosis, and tubular epithelial hyperplasia, even in patients with normal renal function or early renal failure.³³ Sclerosis involves both afferent arterioles and interlobular arteries. This is more prominent in ADPKD than in patients with glomerular disease and comparable renal function and may be attributable to hypertension and the activation of the RAS demonstrated in ADPKD. Interstitial fibrosis is also prominent, even in early disease. It is associated with an interstitial infiltrate of macrophages and lymphocytes.

TREATMENT

Current therapy is directed toward the renal and extrarenal complications of the disease in an effort to limit morbidity and mortality. Advances in the understanding of the genetics of ADPKD and mechanisms of cyst development and growth have raised hopes for treatments specifically directed toward limiting the development and progression of the disease, and some of these treatments are now being evaluated in clinical trials (see later, *Novel Therapies*).

Flank Pain

Causes of flank pain that may require intervention, such as infection, stone, and tumor, should be excluded. Care should be taken to avoid long-term administration of nephrotoxic agents, such as combination analgesics and nonsteroidal anti-inflammatory drugs. Narcotic analgesics should be reserved for the management of acute pain. Patients with chronic kidney pain are at risk for narcotic and analgesic dependence, and a psychological evaluation and a supportive attitude on the part of the physician are essential. Reassurance, lifestyle modification, and avoidance of aggravating activities may be helpful. Tricyclic antidepressants are helpful as in other chronic pain syndromes, with a generally well tolerated side-effect profile. Splanchnic nerve blockade with local anesthesia or corticosteroids results in pain relief prolonged beyond the duration of the local anesthetic.

When distortion of the kidneys by large cysts is deemed responsible for the pain and conservative measures fail, cyst decompression should be considered. Cyst aspiration, under ultrasound or CT guidance, is a relatively simple procedure; to prevent the reaccumulation of cyst fluid, sclerosing agents such as 95% ethanol or acidic solutions of minocycline are commonly used, with a success rate of greater than 90%. Minor complications include microscopic hematuria, localized pain, transient fever, and

systemic absorption of the alcohol. More serious complications, such as pneumothorax, perirenal hematoma, arteriovenous fistula, urinoma, and infection, are rare. Complications from aspiration of centrally located cysts are more common, and the morbidity of the procedure is proportional to the number of cysts treated.

If multiple cysts are contributing to pain, laparoscopic or surgical cyst fenestration may be of benefit. Surgical decompression is effective in 80% to 90% of patients at 1 year, and 62% to 77% have sustained pain relief for more than 2 years (Fig. 44.12A). Surgical intervention does not accelerate the decline in renal function, as once thought, but does not appear to preserve declining renal function either (Fig. 44.12B). Laparoscopic fenestration is as effective as open surgical fenestration in short-term follow-up in patients with limited disease, and there is a shorter, less complicated recovery period compared with open surgery. Previous abdominal surgery with possible adhesion formation is a relative contraindication to the procedure.

There are a number of other interventions for the management of pain in ADPKD whose roles have not been fully defined. Laparoscopic renal denervation has been used in combination with cyst fenestration and may be considered, particularly in polycystic kidneys without large cysts. A nonrandomized, open label, uncontrolled trial of videothoracoscopic sympathectomy is under way (www.clinicaltrials.gov, NCT00571909). Laparoscopic and retroperitoneoscopic nephrectomy and arterial embolization have been used to treat symptomatic polycystic kidneys in ADPKD patients with ESRD.

Cyst Hemorrhage

Episodes of cyst hemorrhage are self-limited and respond well to conservative management with bed rest, analgesics, and adequate fluid intake to prevent obstructing clots. Rarely, bleeding is more severe, with extensive subcapsular or retroperitoneal hematoma causing significant decrease in hematocrit and hemodynamic instability. This requires hospitalization and transfusion. In cases of unusually severe or persistent hemorrhage, segmental arterial embolization can be successful. If not, surgery may be required to control bleeding.

Urinary Tract and Cyst Infection

Because most renal cyst infections begin as cystitis, prompt treatment of symptomatic cystitis and asymptomatic bacteriuria is indicated to prevent retrograde seeding of the renal parenchyma. Antibiotics that require glomerular filtration, such as highly

polar aminoglycosides, are not effective for upper urinary tract infection in severe renal impairment. Cyst infection is often difficult to treat despite prolonged therapy with an antibiotic to which the organism is susceptible. Treatment failure occurs if antibiotics do not penetrate the cyst epithelium and achieve therapeutic concentrations within the cysts. With gradient cysts, the epithelium lining the cyst has functional and ultrastructural characteristics of the distal tubule epithelium. Penetration is through tight junctions, allowing only lipid-soluble agents access. Nongradient cysts, which are more common, allow solute access through diffusion, suggesting that water-soluble agents should gain entry to the cysts. However, kinetic studies indicate that these agents penetrate nongradient cysts slowly and irregularly, giving rise to unreliable drug concentrations within the cysts. Lipophilic agents have been shown to penetrate both gradient and nongradient cysts equally and reliably and have a pK_a that allows favorable electrochemical gradients into acidic cyst fluid. Therapeutic agents of choice include trimethoprim-sulfamethoxazole and fluoroquinolones, both of which have shown favorable intracystic therapeutic concentration gradients at physiologic pH in gradient and nongradient cysts.

If fever persists after 1 to 2 weeks of appropriate antimicrobial therapy, percutaneous or surgical drainage of infected cysts should be undertaken. In the case of end-stage polycystic kidneys, nephrectomy should be considered. If fever recurs after stopping of antibiotics, complicating features such as obstruction, perinephric abscess, and stone should be excluded. If no such complicating features are identified, the antibiotic course should be extended and may require several months to fully eradicate infection.

Nephrolithiasis

Treatment of nephrolithiasis in patients with ADPKD is not different from that in patients without ADPKD. Potassium citrate is the treatment of choice in the three stone-forming conditions associated with ADPKD: uric acid lithiasis, hypocitraturic calcium oxalate nephrolithiasis, and distal acidification defects. Extracorporeal shock wave lithotripsy and percutaneous nephrostolithotomy are reported to be 82% and 80% successful, respectively, without significant complication.³⁴

Hypertension

Control of hypertension is essential because uncontrolled hypertension accelerates the decline in renal function and aggravates extrarenal complications. Antihypertensive agents of choice and optimal blood pressure targets in ADPKD have not been established. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) increase renal blood flow in ADPKD, have a low side effect profile, and may have renoprotective properties that go beyond blood pressure control. Although studies have failed to demonstrate a beneficial effect of ACE inhibitors on the progression of ADPKD,³⁵⁻³⁸ these studies have been limited by the use of low drug dosages, small numbers of patients, short duration of follow-up, and inclusion of patients with widely different renal function. An extended follow-up of ADPKD patients in the Modification of Diet in Renal Disease (MDRD) study showed a delayed onset of kidney failure and lower composite outcome of kidney failure and all-cause mortality in the low blood pressure group (51% of them taking ACE inhibitors) compared with those in the usual blood pressure group (32% of them taking ACE inhibitors).³⁹ An ongoing study

(HALT PKD) is designed to determine whether combined therapy with an ACE inhibitor and an ARB is superior to an ACE inhibitor alone in delaying the progression of the cystic disease in patients with preserved renal function or in slowing the decline of renal function in patients with chronic kidney disease stage 3. HALT PKD will also determine whether a low blood pressure target is superior to a standard blood pressure target in patients with preserved renal function. Although these definitive studies are needed, on available evidence, we recommend tight blood pressure control to 125/75 mm Hg with a regimen that includes ACE inhibitors or ARBs.

Progressive Renal Failure

General strategies to delay progression of chronic kidney disease are discussed in Chapter 76. A subgroup analysis of the MDRD trial, however, showed no beneficial effect on renal function in ADPKD of strict compared with standard blood pressure control and marginal benefit of a very low protein diet. Because these interventions were introduced late in that study (GFR 13 to 55 ml/min per 1.73 m²), these results do not exclude a beneficial effect of earlier interventions. The benefit of avoiding high fluid intake in ADPKD remains controversial.⁴⁰

ADPKD patients do better on dialysis than patients with ESRD from other causes. Women appear to do better than men. The good outcome in ADPKD may be due to higher endogenous erythropoietin production and better maintenance of hemoglobin, or lower comorbidity. Rarely, hemodialysis can be complicated by intradialytic hypotension if there is inferior vena cava compression by a medially located renal cyst. Despite renal size, peritoneal dialysis can usually be performed in ADPKD, although there is increased risk for inguinal and umbilical hernias, which require surgical repair.

Polycystic Liver Disease

PLD is usually asymptomatic and requires no treatment. When it is symptomatic, therapy is directed toward reducing cyst volume and hepatic size. Noninvasive measures include avoiding ethanol, other hepatotoxins, and possibly cAMP agonists (e.g., caffeine), which have been shown to stimulate cyst fluid secretion *in vitro*. Histamine H₂ blockers and somatostatin have been suggested to reduce secretion of secretin and secretory activity of cyst walls. Estrogens are likely to contribute to cyst growth, but the use of oral contraceptive agents and postmenopausal estrogen replacement therapy are contraindicated only if the liver is significantly enlarged and the risk for further hepatic cyst growth outweighs the benefits of estrogen therapy. Rarely, symptomatic PLD may require invasive measures to reduce cyst volume and hepatic size. Options include percutaneous cyst aspiration and sclerosis, laparoscopic fenestration, and open surgical fenestration. Cyst aspiration is the procedure of choice if symptoms are caused by one or a few dominant cysts or by cysts that are easily accessible to percutaneous intervention. To prevent the reaccumulation of cyst fluid, sclerosis with minocycline or 95% ethanol is often successful. Laparoscopic fenestration can be considered for large cysts that are more likely to recur after ethanol sclerosis or if several cysts are present that would require multiple percutaneous passes to be treated adequately. Partial hepatectomy with cyst fenestration is an option because PLD often spares a part of the liver with adequate preservation of hepatic parenchyma and liver function (see Fig. 44.13). In the rare case in which no segments are spared, liver transplantation may be necessary.⁴¹

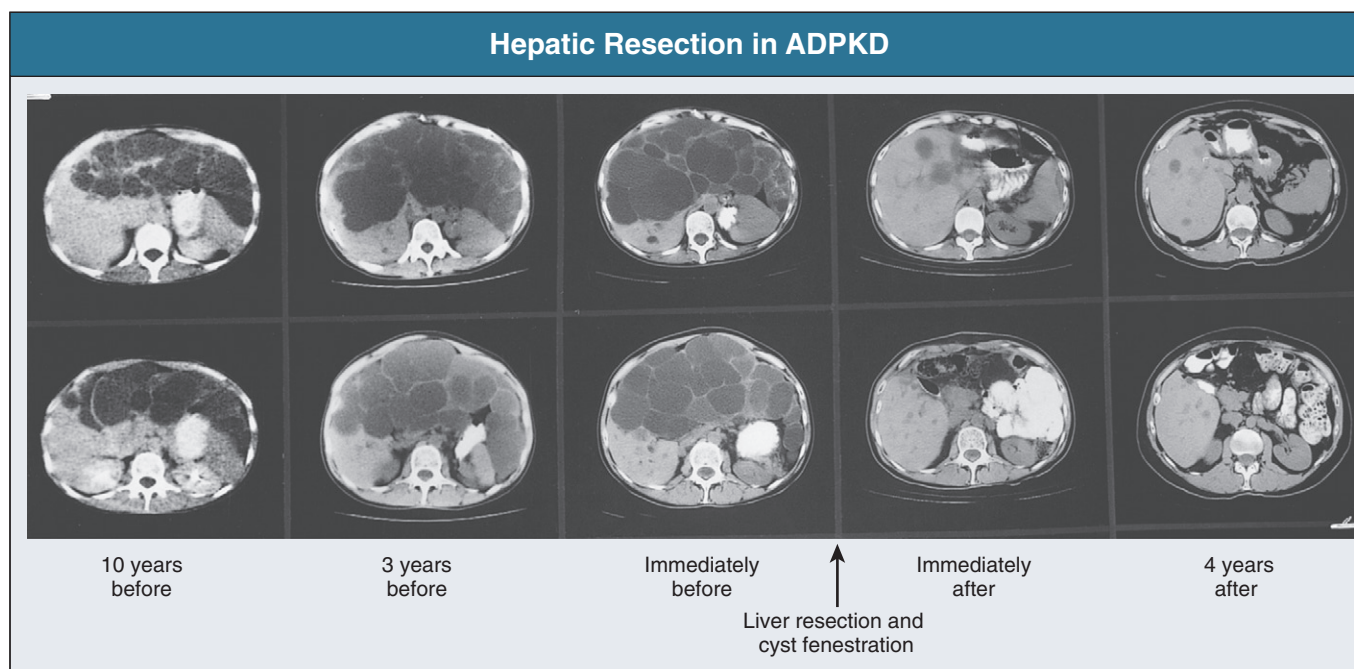

Figure 44.13 Hepatic resection in ADPKD. CT scans of the abdomen 10 years before (column 1), 3 years before (column 2), immediately before (column 3), immediately after (column 4), and 4 years after (column 5) liver resection and cyst fenestration demonstrating long-term, sustained reduction in liver size after the procedure. (Reprinted with permission from reference 49.)

When a hepatic cyst infection is suspected, any cyst with unusual appearance on an imaging study should be aspirated for diagnostic purposes. The best management is percutaneous cyst drainage in combination with antibiotic therapy. Long-term oral antibiotic suppression or prophylaxis should be reserved for relapsing or recurrent cases. Antibiotics of choice are trimethoprim-sulfamethoxazole and the fluoroquinolones, which are effective against the typical infecting organisms and concentrate in the biliary tree and cysts.

Intracranial Aneurysm

Ruptured or symptomatic intracranial aneurysm requires surgical clipping of the neck of the aneurysm. Asymptomatic aneurysms measuring less than 5 mm, diagnosed by presymptomatic screening, can be observed with repeated MR angiography at 6 months, then annually and less frequently after stability of the aneurysm has been established. If the size increases, surgery is indicated. Definitive management of aneurysms between 6 and 9 mm remains controversial. Surgical intervention is usually indicated for all unruptured aneurysms 10 mm in diameter or larger. For patients with high surgical risk or with technically difficult lesions, endovascular treatment with detachable platinum coils may be indicated.

NOVEL THERAPIES

A better understanding of the pathophysiology and the availability of animal models have facilitated the development of promising candidate drugs for clinical trials (see Fig. 44.2).

Vasopressin Antagonists

The effect of vasopressin, through V_2 receptors, on cAMP levels in the collecting duct, the major site of cyst development in

ADPKD, and the role of cAMP in cystogenesis provided the rationale for successful preclinical trials of vasopressin V_2 receptor antagonists.² High water intake by itself also exerted a protective effect on the development of PKD in PCK rats, probably because of suppression of vasopressin.⁴² Genetic elimination of arginine vasopressin in these rats yielded animals born with normal kidneys that remained relatively free of cysts unless an exogenous V_2 receptor agonist was administered.⁴³ Phase II clinical trials with tolvaptan have been completed, and a phase III clinical trial is ongoing (NCT00428948).

Somatostatin Analogues

Somatostatin acting on ss_{t2} receptors inhibits cAMP accumulation not only in the kidney but also in the liver. Octreotide, a metabolically stable somatostatin analogue, halted the expansion of hepatic cysts from PCK rats *in vitro* and *in vivo*. Similar effects were observed in the kidneys. Clinical trials of octreotide and lanreotide for PKD and PLD are currently active (NCT00309283, NCT00426153, NCT00565097).

mTOR Inhibitors

The mammalian target of rapamycin (mTOR) is activated in animal models of PKD. Patients with the contiguous *PKD1/TSC2* gene syndrome exhibit a more severe form of PKD than do those with ADPKD alone. This observation suggests a convergence of signaling pathways downstream from PC1 and the TSC proteins tuberlin and hamartin that control the activity of mTOR. Studies in three rodent models of PKD have shown that the mTOR inhibitors sirolimus and everolimus significantly retard cyst expansion and protect renal function.⁴⁴ Small retrospective studies of ADPKD patients after transplantation have shown a significant reduction in the volume of the polycystic kidneys or polycystic liver in patients treated

with sirolimus compared with patients treated with calcineurin inhibitors.^{45,46} However randomized trials using everolimus and sirolimus for 18-24 months have not consistently delayed the increase in kidney size nor slowed the decline in progressive renal impairment.^{50,51}

Other strategies targeting molecular mechanisms that are altered in PKD have shown promising results in animal studies but have not yet been assessed in clinical studies. These include activators of the polycystin 2 calcium channel (triptolide) and AMP-activated protein kinase (metformin) and inhibitors or antagonists of transporters and channels required for chloride secretion (CFTR inhibitors). Other promising agents are inhibitors of recycling of potassium out of the cell (KCa3.1 inhibitor), tyrosine kinase receptors (ErbB1, ErbB2, VEGF), tumor necrosis factor receptor, Src, MEK, cyclin-dependent kinases, cyclooxygenase 2, E-prostanoid 2 receptor, 20-hydroxyecosatetraenoic acid synthesis, and caspases (see Fig. 44.2).²

TRANSPLANTATION

Transplantation is the treatment of choice for ESRD in ADPKD. There is no difference in patient or graft survival between ADPKD patients and other ESRD populations. Living donor transplants also have graft survival no different from that of non-ADPKD populations. However, living related transplantation has only recently been widely practiced in the ADPKD population. In 1999, 30% of kidney transplants for ADPKD patients were from living donors, compared with 12% in 1990.

Complications after transplantation are no greater in the ADPKD population than in the general population, and specific complications directly related to ADPKD are rare. Cyst infection is not increased after transplantation, and there is no significant increase in the incidence of symptomatic mitral valve prolapse or hepatic cyst infection. One study showed an increased rate of diverticulosis and bowel perforation in ADPKD. Whether ADPKD increases the risk for development of new-onset diabetes mellitus after transplantation is controversial.

Although practiced routinely in the past, pretransplantation nephrectomy has fallen out of favor. Indications for nephrectomy include a history of infected cysts, frequent bleeding, severe hypertension, and massive renal enlargement with extension into the pelvis. There is no evidence for an increased risk for development of renal cell carcinoma in native ADPKD kidneys after transplantation. When nephrectomy is indicated, hand-assisted laparoscopic nephrectomy is associated with less intraoperative blood loss, less postoperative pain, and faster recovery compared with open nephrectomy and is increasingly being used.

Other Cystic Kidney Diseases

Lisa M. Guay-Woodford

In addition to autosomal dominant polycystic kidney disease (ADPKD), there are numerous other disorders that share renal cysts as a common feature (Fig. 45.1).¹ These disorders may be inherited or acquired; their manifestations may be confined to the kidney or expressed systemically. They may present at a wide range of ages, from the perinatal period to old age (Fig. 45.2). The renal cysts may be single or multiple, and the associated renal morbidity may range from clinical insignificance to progressive parenchymal destruction with resultant renal impairment.

The clinical context often helps distinguish these renal cystic disorders from one another. Echogenic, enlarged kidneys in a neonate or infant should raise suspicion about autosomal recessive polycystic kidney disease (ARPKD), ADPKD, tuberous sclerosis complex, or one of the many congenital syndromes associated with renal cystic disease. Renal impairment in an adolescent suggests juvenile nephronophthisis–medullary cystic disease complex and ARPKD as possible causes. The finding of a solitary cyst in a 5-year-old may indicate a calyceal diverticulum, whereas this finding in a 50-year-old is most compatible with a simple renal cyst. Renal stones occur in ADPKD and medullary sponge kidneys. For those disorders with systemic manifestations, such as ADPKD, tuberous sclerosis complex, and von Hippel–Lindau disease, the associated extrarenal features may provide other important differential diagnostic clues.

For an increasing number of conditions, genetic testing is available in expert laboratories around the world. These are listed at <http://www.genetests.org>.

AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

Definition

ARPKD is an inherited malformation complex with varying degrees of renal collecting duct dilation, biliary ductal ectasia, and associated fibrosis.²

Genetic Basis of ARPKD

All typical forms of ARPKD are caused by mutations in a single gene, *PKHD1* (polycystic kidney and hepatic disease), which encodes multiple alternatively spliced isoforms predicted to form both membrane-bound and secreted proteins.³ The largest protein product of *PKHD1*, termed fibrocystin/polyductin complex (FPC), contains one membrane spanning domain and an intracellular C-terminal tail. FPC localizes, at least in part, to the primary cilium and the centrosome in renal epithelial cells.⁴

The basic defects observed in ARPKD suggest that FPC mediates the terminal differentiation of the collecting duct and biliary tract. However, the exact function of the numerous isoforms has not been defined, and the widely varying clinical spectrum of ARPKD may depend, in part, on the nature and number of splice variants that are disrupted by specific *PKHD1* mutations.

Pathogenesis

ARPKD typically begins *in utero*, and the renal cystic lesion appears to be superimposed on a normal developmental sequence. The tubular abnormality primarily involves fusiform dilation of the collecting ducts. Detailed microdissection studies have excluded tubular obstruction as a primary pathogenic mechanism. The biliary lesion appears to involve defective remodeling of the ductal plate *in utero*. As a result, primitive bile duct configurations persist and progressive portal fibrosis evolves.⁵ The remainder of the liver parenchyma develops normally. The defect in ductal plate remodeling is accompanied by abnormalities in the branching of the portal vein. The resulting histopathologic pattern is referred to as congenital hepatic fibrosis.

The primary cilium plays a central role in the pathogenesis of hepatorenal fibrocystic diseases.⁶ The weight of the experimental evidence from human ARPKD and animal model studies suggests that ciliary dysfunction contributes to a maturational arrest in both renal and biliary tubuloe epithelial differentiation.

Epidemiology

The estimated incidence of ARPKD is 1 per 20,000 live births.⁷ It occurs more frequently in Caucasians than in other ethnic populations.

Clinical Manifestations

The clinical spectrum of ARPKD is variable and depends on the age at presentation. The majority of cases are identified either *in utero* or at birth. The most severely affected fetuses have enlarged echogenic kidneys and oligohydramnios due to poor fetal urine output. These fetuses develop the Potter phenotype, with pulmonary hypoplasia, a characteristic facies, and deformities of the spine and limbs. At birth, these neonates often have a critical degree of pulmonary hypoplasia that is incompatible with survival. The estimated perinatal mortality is about 30%. Renal function, although frequently compromised, is rarely a cause of neonatal death.

For those who survive the first month of life, the reported mean 5-year patient survival rate is 85% to 90%.^{2,8} Morbidity

and mortality result from severe systemic hypertension, renal impairment, and portal hypertension due to portal tract hyperplasia and fibrosis.^{2,8,9} Hypertension usually develops in the first few months and ultimately affects 70% to 80% of patients. ARPKD patients have defects in both urinary diluting capacity and concentrating capacity. Newborns can have hyponatremia.

Whereas net acid excretion may be reduced, metabolic acidosis is not a significant clinical feature. Abnormal urinalysis is common in both infants and older children.² Microscopic or gross hematuria, proteinuria, and sterile pyuria have all been reported. Two retrospective studies have noted an increased incidence of culture-confirmed urinary tract infections.

In the first 6 months of life, ARPKD infants may have a transient improvement in glomerular filtration rate (GFR) due to renal maturation. Subsequently, a progressive but variable decline in renal function occurs, with some patients not progressing to end-stage renal disease (ESRD) until adolescence or early adulthood. With advances in effective therapy for ESRD, prolonged survival is common, and the hepatic complications become the dominant clinical issue for many patients.

On average, those infants with serum creatinine values above 2.2 mg/dl (200 μmol/l) progress to ESRD within 5 years, but this is highly variable. In longitudinal studies, the probability of renal survival without ESRD is ~85% at 1 year, ~70% at 10 years, ~65% at 15 years, and ~40% at 20 years.^{8,9}

In children who present later in childhood or in adolescence, portal hypertension is frequently the predominant clinical abnormality, with hepatosplenomegaly and bleeding esophageal or gastric varices as well as hypersplenism with consequent thrombocytopenia, anemia, and leukopenia. Hepatocellular function is usually preserved. Ascending suppurative cholangitis is a serious complication and can cause fulminant hepatic failure.¹⁰

Pathology

Kidney

The renal involvement is invariably bilateral and largely symmetric. The histopathology varies according to the age at presentation and the extent of cystic involvement (Fig. 45.3A, B).

In the affected neonate, the kidneys can be 10 times normal size but retain their reniform configuration. Dilated, fusiform collecting ducts extend radially through the cortex. In the medulla, the dilated collecting ducts are more often cut tangentially or transversely. Up to 90% of the collecting ducts are involved. Associated interstitial fibrosis is minimal in neonates and infants but increases with progressive disease.

In patients diagnosed later in childhood, the kidney size and extent of cystic involvement tend to be more limited. Cysts can expand up to 2 cm in diameter and assume a more spherical configuration. Progressive interstitial fibrosis is probably responsible for secondary tubular obstruction. In older children, medullary ductal ectasia is the predominant finding.

Cysts are lined with a single layer of nondescript cuboidal epithelium. The glomeruli and nephron segments proximal to the collecting ducts are initially structurally normal but are often crowded between ectatic collecting ducts or displaced into subcapsular wedges. The presence of cartilage or other dysplastic elements indicates a diagnosis other than ARPKD, such as cystic dysplasia.

Liver

The liver lesion in ARPKD is characterized by ductal plate malformation.⁵ The liver can be either normal in size or somewhat enlarged. Bile ducts are dilated (biliary ectasia), and marked cystic dilation of the entire intrahepatic biliary system (Caroli's disease) has been described. In neonatal ARPKD, the bile ducts are increased in number, tortuous in configuration, and often located around the periphery of the portal tract. In older children, the biliary ectasia is accompanied by increasing portal tract

Figure 45.3 Pathologic features of ARPKD. **A**, Cut section: ARPKD kidney from 1-year-old child reveals discrete medullary cysts and dilated collecting ducts. **B**, Light microscopy: later-onset ARPKD kidney with prominent medullary ductal ectasia. (Hematoxylin and eosin; magnification $\times 10$.) **C**, Light microscopy: congenital hepatic fibrosis. fibrosis and hypoplasia of the small portal vein branches (Fig. 45.3C). The hepatic parenchyma may be intersected by delicate fibrous septa that link the portal tracts, but the hepatocytes themselves are seldom affected.

Diagnosis

ARPKD must be differentiated from a range of other pediatric renal cystic disorders (Fig. 45.4).

Imaging

In the past decade, clinical diagnosis has increasingly relied on imaging instead of histopathologic analysis.

ARPKD belongs to a group of disorders described as hepatorenal fibrocystic diseases.¹¹ Whereas most of these disorders are characterized by large, echogenic kidneys in the fetus and neonate, studies indicate that to a large extent they can be distinguished by ultrasound.¹²

ARPKD kidneys *in utero* are hyperechogenic and display decreased corticomedullary differentiation because of the hyperechogenic medulla (Fig. 45.5A). With high-resolution ultrasound, the radial array of dilated collecting ducts may be imaged. In comparison, ADPKD kidneys *in utero* tend to be moderately enlarged with a hyperechogenic cortex and relatively hypoechogenic medulla, causing increased corticomedullary differentiation.

Kidney size typically peaks at 1 to 2 years of age, then gradually declines relative to the child's body size and stabilizes by 4 to 5 years. As patients age, there is increased medullary echogenicity with scattered small cysts, measuring less than 2 cm in diameter. These cysts and progressive fibrosis can alter the reniform contour, causing ARPKD in some older children to be mistaken for ADPKD. Contrast-enhanced computed tomography (CT) can be useful in delineating the renal architecture in these children (Fig. 45.5B). Bilateral pelvicaliectasis and renal calcifications have been reported in 25% and 50% of ARPKD patients, respectively.^{9,13} In adults with medullary ectasia alone, the cystic lesion may be confused with medullary sponge kidney.

The liver may be either normal in size or enlarged. It is usually less echogenic than the kidneys. Prominent intrahepatic bile duct dilation suggests associated Caroli's disease. With age, the portal fibrosis tends to progress, and in older children, ultrasound typically shows hepatosplenomegaly and a patchy increase in hepatic echogenicity.

Genetic Testing

With the identification of *PKHD1* as the principal disease gene in ARPKD, genetic testing is available as a clinical diagnostic tool. The mutation detection rate is 80% to 87%. Current diagnostic algorithms include gene-based analysis and haplotype-based genotyping in informative families (<http://www.genetests.org/>). Genetic testing is primarily applied in the context of prenatal testing¹⁴ and preimplantation genetic diagnosis.¹⁵ To date, there is limited evidence for genotype-phenotype correlations, although patients with two truncating mutations have a higher risk of perinatal demise.^{16,17} There is a high percentage of unique, missense changes in *PKHD1*, which can complicate the unequivocal interpretation of gene-based testing. Moreover, about 20% of ARPKD siblings have discordant clinical phenotypes.⁸ These data potentially complicate genetic counseling, and caution must be exercised in predicting the clinical outcome of future affected children.

Treatment

The survival of ARPKD neonates has improved significantly in the last two decades because of advances in mechanical ventilation for neonates and other supportive measures. Aggressive interventions, such as unilateral or bilateral nephrectomies and continuous hemofiltration, have been advocated in neonatal management, but prospective, controlled studies have yet to be performed.

For those children who survive the perinatal period, careful blood pressure monitoring is required. Angiotensin-converting enzyme (ACE) inhibitors, calcium channel blockers, β -blockers, and loop diuretics are effective antihypertensive agents. The management of ARPKD children with declining GFR should follow the standard guidelines established for chronic kidney disease (CKD) in children.¹⁸

Given the relative urinary concentrating defect, ARPKD children should be monitored for dehydration during intercurrent illnesses associated with fever, tachypnea, nausea, vomiting, or diarrhea. In those infants with severe polyuria, thiazide diuretics may be used to decrease distal nephron solute and water delivery. Acid-base balance should be closely monitored and supplemental bicarbonate therapy initiated as needed.

Close monitoring for portal hypertension is warranted in all ARPKD patients. The severity of portal hypertension and its progression can be followed by serial ultrasound and Doppler flow studies. Hematemesis or melena suggests the presence of

Figure 45.4 Features of pediatric renal cystic disease.¹ Meckel-Gruber syndrome is a severe, often lethal, autosomal recessive disorder characterized by bilateral renal cystic dysplasia, biliary ductal dysgenesis, bilateral postaxial polydactyly, and variable central nervous system malformations. The triad of renal cystic disease, occipital encephalocele, and polydactyly is most common. ²Glomerulocystic kidney disease (GCKD) can occur as the infantile manifestation of ADPKD. Familial hypoplastic GCKD, due to mutations in *TCF2*, the gene encoding hepatocyte nuclear factor 1 β , can be associated with maturity-onset diabetes of the young, type 5 (MODY5). ³A contiguous germline deletion of both the *PKD1* and *TSC2* genes (the PKTS contiguous gene syndrome) occurs in a small group of patients with features of TSC as well as massive renal cystic disease reminiscent of ADPKD, severe hypertension, and a progressive decline in renal function with the onset of ESRD in the second or third decade of life. ⁴Joubert syndrome (JBTS; MIM 213300) is a genetically heterogeneous (JBTS1-7), autosomal recessive disorder characterized by developmental defects in the cerebellum (cerebellar vermis aplasia) and the eye (coloboma) as well as retinitis pigmentosa, congenital hypotonia, and either ocular motor apraxia or irregularities in breathing patterns during the neonatal period. The disease can be associated with NPHP, and mutations in *NPHP1* have been described in a small subset of patients (JBTS4). Disease genes have been identified for JBTS3 and JBTS5-7. ⁵Listed at GeneTests (<http://www.genetests.org>). High-resolution ultrasound reveals radially arrayed dilated collecting ducts. **B**, ARPKD in a symptomatic 4-year-old girl. Contrast-enhanced CT shows a striated nephrogram and prolonged corticomedullary differentiation.

esophageal varices. Medical management may include sclerotherapy, variceal banding, or transjugular intrahepatic portosystemic shunt. Surgical approaches, such as portocaval or splenorenal shunting, may be indicated in some patients. Although hypersplenism occurs fairly commonly, splenectomy is seldom warranted. Unexplained fever with or without elevated transaminase levels suggests bacterial cholangitis and requires meticulous evaluation, sometimes including a percutaneous liver biopsy, to make the diagnosis and to guide aggressive antibiotic therapy.

Effective management of systemic and portal hypertension, coupled with successful renal replacement therapy, has allowed long-term patient survival. Therefore, the prognosis in ARPKD, particularly for those children who survive the first month of life, is far less bleak than popularly thought, and aggressive medical therapy is warranted.

Transplantation

A prolonged period of dialysis in childhood has been associated with both cognitive and educational impairment. Therefore, renal transplantation is the treatment of choice for ESRD in ARPKD patients, and at least one report advocates preemptive nephrectomy in neonates with markedly enlarged kidneys.¹⁹ Because ARPKD is a recessive disorder, either parent may be a suitable kidney donor. Native nephrectomies may be warranted in patients with massively enlarged kidneys to allow allograft placement.

In some patients, combined kidney-liver transplantation is appropriate.²⁰ Indications include the combination of renal failure and either recurrent cholangitis or significant complications of portal hypertension (e.g., recurrent variceal bleeding, refractory ascites, and the hepatopulmonary syndrome). In addition, liver transplantation may be a reasonable option for patients with a single episode of cholangitis in the context of marked abnormalities in the biliary system (Caroli's syndrome).²¹

JUVENILE NEPHRONOPHTHISIS–MEDULLARY CYSTIC DISEASE COMPLEX

Definitions

Juvenile nephronophthisis (NPHP) and medullary cystic kidney disease share the same triad of histopathologic features: tubular basement membrane irregularities, tubular atrophy with cyst formation, and interstitial cell infiltration with fibrosis. These histopathologically similar disorders differ only in their mode of transmission, age at onset, and genetic defects. Juvenile NPHP is an autosomal recessive disorder that presents in childhood. Medullary cystic disease is an autosomal dominant disorder that occurs in adults. The inclusive term *juvenile nephronophthisis–medullary cystic disease complex* has been used to describe these disorders. However, juvenile NPHP is far more common than medullary cystic disease and has been reported both as an isolated renal disease and in association with retinitis pigmentosa, congenital hepatic fibrosis, oculomotor apraxia, and skeletal anomalies. Therefore, these entities are considered separately.

Autosomal Recessive Juvenile Nephronophthisis

Genetic Basis of Nephronophthisis

Nine genes (*NPHP1*–*NPHP9*) involved in juvenile NPHP have been identified.²² Defects in *NPHP1* account for 21% of NPHP,

with large, homozygous deletions detected in 80% of affected family members and in 65% of sporadic cases. Mutations in each of the remaining NPHP genes cause no more than 3% of NPHP-related disease. Clinical disease expression seems to be exacerbated by oligogenic inheritance, that is, patients carrying two mutations in a single NPHP gene as well as a single-copy mutation in an additional NPHP gene. In addition, multiple allelism, or distinct mutations in a single gene, appears to explain the continuum of multiorgan phenotypic abnormalities observed in NPHP, Meckel syndrome, and Joubert syndrome.

The *NPHP1* and *NPHP3*–*5* genes encode novel cytosolic proteins that are collectively called the nephrocystins. The *NPHP2* gene, involved in infantile NPHP, encodes inversin, a protein that localizes in a cell cycle–dependent manner to different subcellular locations. When it is expressed at the basal body of the primary cilium, inversin has been shown to regulate the Wnt signaling pathway. The gene products encoded by *NPHP6/CEP290*, *NPHP8/RPGRIPL*, and *NPHP9/NEK8* are all expressed in or at the base of primary cilia in renal epithelial cells. The *NPHP7/GLIS2* gene encodes the transcription factor Gli-similar protein 2, thus implicating the hedgehog signaling pathway in the pathogenesis of renal cystic diseases.

All of the proteins encoded by *NPHP1*–*9* are expressed in or at the base of primary cilia in renal epithelial cells, giving rise to a unifying theory that defines cystic kidney diseases as “ciliopathies.”²² However, the subcellular localization of these proteins is not confined to the cilium. For example, nephrocystin and nephrocystin 4 have also been localized to cell junctions and shown to interact with components of cell-cell and cell-matrix interaction complexes. These observations suggest that NPHP proteins may have multiple functions, depending on their localization in different cell compartments and their association with distinct protein complexes.

Clinical Manifestations

Renal Disease NPHP accounts for 5% to 15% of ESRD in children and adolescents. Three distinct forms of the disease (infantile, juvenile, and adolescent) have been described on the basis of the age at onset of ESRD. However, further clinical, pathologic, and genetic analyses indicate that the adolescent and juvenile forms are virtually indistinguishable and should be described with the single designation juvenile NPHP.²³ In juvenile NPHP (the most common form), ESRD occurs at a mean age of 13 years; in the infantile form, the onset of ESRD consistently occurs before 5 years of age.

Decreased urinary concentrating capacity is invariable in NPHP and usually precedes the decline in renal function, with onset between 4 and 6 years of age. Polyuria and polydipsia are common. Salt wasting develops in most patients with renal impairment, and sodium supplementation is often required until the onset of ESRD. One third of patients become anemic before the onset of renal impairment, and this has been attributed to a defect in the functional regulation of erythropoietin production by peritubular fibroblasts.²⁴ Growth retardation, out of proportion to the degree of renal impairment, is a common finding.

Slowly progressive decline in renal function is typical of juvenile NPHP. Whereas symptoms can be detected after the age of 2 years, they may progress insidiously, such that 15% of affected patients are recognized only after ESRD has developed. There is no specific treatment. The disease is not known to recur in renal allografts.

Children with the infantile variant develop symptoms in the first few months of life and rapidly progress to ESRD, usually

before the age of 2 years but invariably by 5 years of age. Severe hypertension is common in this disorder. This disorder is a distinct genetic entity with a characteristic renal histopathology and has not been reported in sibships with classic juvenile NPHP.²⁵

Unlike patients with polycystic kidney disease or medullary sponge kidney, NPHP patients rarely develop flank pain, hematuria, hypertension, urinary tract infections, or renal calculi.

Associated Extrarenal Abnormalities Extrarenal abnormalities have been described in approximately 10% to 15% of juvenile NPHP patients.²³ The most frequently associated anomaly is retinal dystrophy due to tapetoretinal degeneration (Senior-Loken syndrome). Severely affected patients present with coarse nystagmus, early blindness, and a flat electroretinogram (Leber amaurosis); those with moderate retinal dystrophy typically have mild visual impairment and retinitis pigmentosa. Other extrarenal anomalies include oculomotor apraxia (Cogan syndrome), cerebellar vermis aplasia (Joubert syndrome), and cone-shaped epiphyses of the bones. Congenital hepatic fibrosis occurs occasionally in NPHP patients, but the associated bile duct proliferation is mild and qualitatively different from that found in ARPKD.

Pathology

In juvenile NPHP, the kidneys are moderately contracted with parenchymal atrophy, causing a loss of corticomedullary demarcation. Histopathologic findings include tubular atrophy with thickened tubular basement membrane, diffuse and severe interstitial fibrosis, and cysts of variable size distributed in an irregular pattern at the corticomedullary junction and in the outer medulla. However, up to 25% of NPHP kidneys have no grossly visible cysts.

In the typical NPHP renal lesion, clusters of atrophic tubules alternate either with groups of viable tubules showing dilation or with marked compensatory hypertrophy or with groups of collapsed tubules. Multilayered thickening of tubular basement membranes is a prominent histopathologic feature (Fig. 45.6). Whereas this histopathologic pattern is not unique, the abrupt transition from one type of tubular profile to another is suggestive of NPHP. Moderate interstitial fibrosis, usually without a significant inflammatory cell infiltrate, is interspersed among the atrophic tubules. Spherical, thin-walled cysts lined with a simple

Figure 45.6 Renal pathology in juvenile nephronophthisis. Light microscopy: tubulointerstitial nephropathy. Atrophic tubules with irregularly thickened basement membranes are surrounded by interstitial fibrosis. Dilated tubules are evident at the corticomedullary junction. (Hematoxylin and eosin; magnification $\times 40$.)

cuboidal epithelium may be evident at the corticomedullary junction, in the medulla, and even in the papillae. Microdissection studies indicate that these cysts arise from the loop of Henle, distal convoluted tubules, and collecting ducts. Glomeruli may be normal, although some may be completely sclerosed; others may show periglomerular fibrosis, and still others dilation of Bowman's space.

In comparison, the infantile form has features of both juvenile NPHP (such as tubular cell atrophy, interstitial fibrosis, and tubular cysts) and polycystic kidney disease, including enlarged kidneys and widespread cystic involvement.²⁶

Diagnosis and Differential Diagnosis

In a child with NPHP and renal impairment, ultrasound reveals normal-sized or small kidneys with increased echogenicity and loss of corticomedullary differentiation. On occasion, cysts can be detected at the corticomedullary junction or in the medulla. Thin-section CT scanning may be more sensitive than ultrasound in detecting these cysts.

The pathologic findings in NPHP are not unique; hence, in the early stages of the disease, neither renal imaging nor histopathology can confirm the clinical diagnosis. As an alternative strategy, molecular testing has become increasingly useful in establishing the diagnosis of NPHP, with use of an algorithm for gene-based diagnosis²⁷ that addresses four critical diagnostic issues: (1) detection of the classic homozygous deletion of *NPHP1*; (2) detection of rare, smaller homozygous deletions of *NPHP1*; (3) testing for a heterozygous deletion; and (4) potential exclusion of linkage to *NPHP1*. Genetic testing is currently available for *NPHP1*-related disease (<http://www.genetests.org/>). As new genes are identified and their relative contribution to the NPHP disease spectrum is determined, mutational algorithms will be expanded to include analyses of these NPHP genes.

Autosomal Dominant Medullary Cystic Kidney Disease

Medullary cystic kidney disease is an autosomal dominant condition that is much rarer than autosomal recessive NPHP but histopathologically indistinguishable. Some patients have had phenotypically unaffected parents but an affected second- or third-degree relative, suggesting that the disease is poorly recognized in affected family members or that there is variable penetrance.

Clinically, medullary cystic kidney disease is distinguished from NPHP by its dominant mode of inheritance, later age at onset, progression to ESRD in the third to fourth decade of life, and lack of associated growth retardation and extrarenal manifestations.

Genetic linkage analyses indicate that defects in at least two loci (*MCKD1* and *MCKD2*) can cause medullary cystic kidney disease. Uremia occurs after 60 years of age in *MCKD1*; whereas in *MCKD2*, progression to ESRD occurs around 30 years of age. Mutations in the gene *UMOD*, which encodes uromodulin or Tamm-Horsfall protein, have been identified in *MCKD2* patients. Subsequently, *UMOD* mutations have also been identified in families with familial juvenile hyperuricemic nephropathy (FJHN; MIM 162000), a dominantly transmitted disorder characterized by medullary cystic kidney disease, hyperuricemia, and gout,²⁸ as well as familial glomerulocystic disease with hyperuricemia (MIM 609886).²⁹

The diagnosis can usually be made on the basis of the family history, the clinical associations of hyperuricemia and gout, and

the ultrasound finding of medullary cysts. Genetic testing is available for *UMOD*-related disease (<http://www.genetests.org/>).

MEDULLARY SPONGE KIDNEY

Definition

Medullary sponge kidney (MSK) is a relatively common disorder characterized by dilated medullary and papillary collecting ducts that give the renal medulla a “spongy” appearance.³⁰

Etiology and Pathogenesis

The occasional presence of embryonal tissue in the affected papillae and coexistence of other urinary tract anomalies suggest that MSK results from a developmental defect in the medullary pyramids. In addition, MSK occurs more frequently in individuals with other congenital defects, (e.g., congenital hemihypertrophy, Beckwith-Wiedemann syndrome, Ehlers-Danlos syndrome, and Marfan syndrome).³⁰

Less than 5% of cases are familial, and a clear genetic basis for MSK has not been established.

Epidemiology

In the general population, the frequency of MSK may be underestimated because some affected individuals remain entirely asymptomatic. Up to 20% of patients with nephrolithiasis have at least a mild degree of MSK, but excretory urography in *unselected* patients indicates a disease frequency of approximately 1 in 5000 individuals.

Clinical Manifestations

MSK disease is asymptomatic unless it is complicated by nephrolithiasis, hematuria, or infection. Symptoms typically begin between the fourth and fifth decades of life, but adolescent presentations have been reported. Stones and granular debris in

MSK patients are composed of either pure apatite (calcium phosphate) or a mixture of apatite and calcium oxalate. Several factors appear to contribute to stone formation, including urinary stasis within the ectatic ducts, hypercalciuria, and hyperoxaluria. Hyperparathyroidism has also been reported.

Hematuria, unrelated to either coexisting stones or infection, may be recurrent. The bleeding is usually asymptomatic, unless gross hematuria causes clot-related colic. Urinary tract infection may occur in association with nephrolithiasis or as an independent event. In those patients with stones, infections are more likely to occur in females than in males.

Approximately one third to one half of MSK patients have hypercalcemia,³⁰ but the mechanism has not been established. Decreased renal concentrating ability and impaired urinary acidification have been reported. In most patients, the acidification defect is not associated with systemic acidosis.

Pathology

The pathologic changes are confined to the renal medullary and intrapapillary collecting ducts. Multiple spherical or oval cysts measuring 1 to 8 mm may be detected in one or more papillae. These cysts may be isolated or may communicate with the collecting system. The cysts are frequently bilateral and often contain spherical concretions composed of apatite. The affected pyramids and associated calyces are usually enlarged, and nephromegaly can result when many pyramids are involved. The renal cortex, medullary rays, calyces, and pelvis appear normal, unless complications, such as pyelonephritis or urinary tract obstruction, become superimposed.

Diagnosis

Abdominal plain radiographs often reveal radiopaque concretions in the medulla (Fig. 45.7A). The diagnosis is established by intravenous urography (Fig. 45.7B). Retention of contrast media by the ectatic collecting ducts appears either as spherical cysts or more commonly as diffuse linear striations, which impart a

Figure 45.7 Radiologic findings associated with medullary sponge kidney. MSK in a 52-year-old symptomatic woman. **A**, Preliminary film shows medullary nephrolithiasis. **B**, Ten-minute film from excretory urography shows clusters of rounded densities in the papillae amid discrete linear opacities (paintbrush appearance). **C**, Nonenhanced CT reveals densely echogenic foci in the medulla.

characteristic blush-like pattern to the papillae, the so-called bouquet of flowers or paintbrush appearance. CT is usually not necessary, but nonenhanced CT may help distinguish MSK from papillary necrosis or even ADPKD (Fig. 45.7C).

Treatment

Asymptomatic patients in whom MSK is detected as an incidental finding require no therapy. Hematuria in the absence of stones or infection requires no intervention. If the tubular ectasia is unilateral and segmental, partial nephrectomy may alleviate recurrent nephrolithiasis and urinary tract infection. However, for the majority of patients who have bilateral disease, medical management is sufficient.

Hypercalciuria is the predominant cause of nephrolithiasis in MSK. The mainstay of treatment is high fluid intake to increase urine output and to reduce the precipitation of calcium salts in ectatic ducts. Patients with documented hypercalciuria may benefit from thiazide diuretics. If thiazides are poorly tolerated or contraindicated, inorganic phosphate therapy may be useful. To avoid struvite stone formation, oral phosphates should *not* be used in patients with previous urinary tract infections caused by urease-producing organisms. Patients who form and pass stones recurrently may require lithotripsy or surgical intervention (see Chapter 57).

Urinary tract infection should be treated with standard antibiotic regimens, and for some patients, prolonged therapy may be warranted. Urease-producing organisms, such as coagulase-negative staphylococcus, are particularly problematic as urinary pathogens in MSK. Positive urine cultures, even with relatively insignificant colony counts, must be vigorously pursued.

With proper management of the clinical complications, the long-term prognosis is excellent. Progression to renal impairment is unusual.

TUBEROUS SCLEROSIS COMPLEX

Definition

Tuberous sclerosis complex (TSC) is an autosomal dominant, tumor-suppressor gene syndrome in which tumor-like malformations, called hamartomas, develop in multiple organ systems, including the kidneys, brain, heart, lungs and skin.

Genetic Basis of Tuberous Sclerosis Complex

TSC results from inactivating mutations in one of two genes, *TSC1* on chromosome 9q32-q34³¹ and *TSC2* on chromosome 16p13, adjacent to the *PKD1* gene.³² Large deletions involving both *PKD1* and *TSC2* can result in the PKD1/TSC2 (PKTS) contiguous gene deletion syndrome.³³

The focal nature of TSC-associated disease and the variability of disease expression even within families have suggested that *TSC1* and *TSC2* function as tumor-suppressor genes.³⁴ The tumor-suppressor gene paradigm hypothesizes that two successive mutations are necessary to inactivate a tumor-suppressor gene and to cause tumor formation. The first mutation, inherited and therefore present in all cells, is necessary but not sufficient to produce tumors. A second mutation occurs after fertilization and is required to induce tumor transformation. The inactivating germline mutations identified in *TSC1* and *TSC2* as well as the loss of heterozygosity detected in 50% of *TSC2*-associated

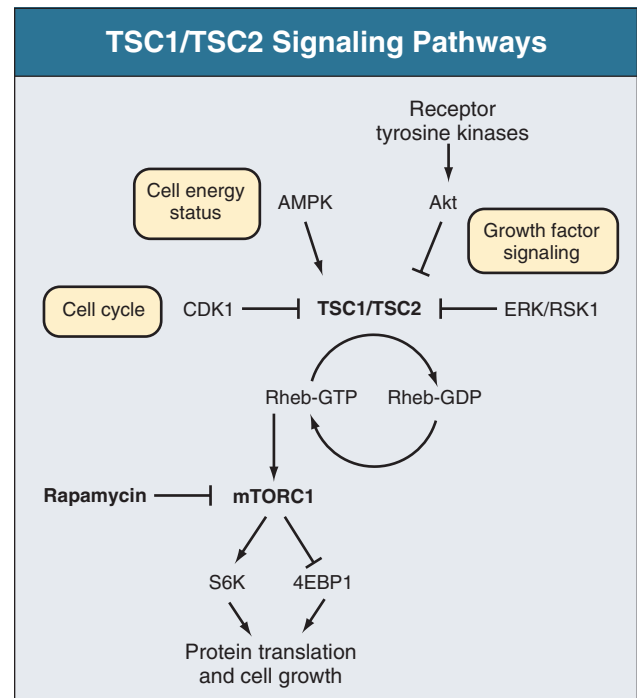

Figure 45.8 TSC1/TSC2 signaling pathways. Hamartin (TSC1) and tuberlin (TSC2) integrate cues from extracellular growth factor binding (through Akt and ERK/RSK1), the intracellular energy status (through AMPK), and the cell cycle (through CDK1) to direct signaling pathways that regulate cellular proliferation, differentiation, and migration.^{34,36} Tuberlin contains a GTPase-activating protein (GAP) domain in its carboxyl terminus, and when it forms a complex with hamartin (TSC1/TSC2 complex), the small GTPase Rheb is converted from its active GTP-bound state to an inactive GDP-bound state. Rheb is an activator of the mTORC1 kinase, which regulates a number of processes linked to protein synthesis and cell growth (through the ribosomal S6 kinases and the eukaryotic initiation factor 4E-binding protein [4EBP1]). mTORC1 is activated physiologically in response to growth factor signaling, which causes phosphorylation of tuberlin, dissociation of the TSC1/TSC2 complex, and increased levels of Rheb-GTP. Inactivation of the TSC1/TSC2 complex through mutations in *TSC1* or *TSC2* leads to inappropriate activation of mTORC1. Rapamycin is an mTOR inhibitor. (Modified with permission from reference 34.)

hamartomas and ~10% of *TSC1*-associated hamartomas support the hypothesis that both *TSC1* and *TSC2* function as tumor-suppressor genes.

The *TSC2* gene product tuberlin interacts with hamartin, the product of the *TSC1* gene. As described in Figure 45.8, the hamartin/tuberlin (TSC1/TSC2) complex functions in multiple cellular pathways, primarily by inhibiting the kinase activity of mTOR, the mammalian target of rapamycin. mTOR functions in a protein complex (mTORC1) to regulate nutrient uptake, cell cycle progression, cell growth, and protein translation.^{35,36}

The *PKD1* gene product polycystin 1 plays a key role in regulating mTORC1 activity by complexing with tuberlin and mTOR, thereby inhibiting the mTOR pathway.³⁷ In normal adult kidney, mTOR is inactive. With loss of function of either polycystin 1 or tuberlin, mTOR activity is upregulated, contributing to dysregulated cell growth and cystogenesis. In addition, hamartin appears to function through TORC1-independent pathways to regulate the structural integrity of the primary cilium, suggesting that ciliary dysfunction is an additional mechanism in TSC pathogenesis.³⁸

Epidemiology

TSC affects 1 in 6000 individuals.³⁵ The disease penetrance is quite variable. About two thirds of TSC patients are sporadic cases with no family history, and the disease apparently results from new mutational events. Among patients with sporadic disease, mutations in *TSC2* are approximately five times more common than mutations in *TSC1*, whereas the ratio is 1:1 in familial cases. *TSC1*-related disease is milder, apparently because of a reduced rate of second hits.

Clinicopathologic Manifestations

The clinical features of *TSC1*- and *TSC2*-linked disease are similar, although *TSC2*-linked disease tends to be more severe. The most common clinical manifestations are seizures, mental retardation or autism, skin lesions, interstitial lung disease, and tumors in the brain, retina, kidney, and heart. In affected individuals older than 5 years, the most common skin lesions are facial angiofibromas (Fig. 45.9), hypomelanotic macules, and ungual fibromas.³⁹

Kidney involvement occurs frequently in TSC; one large study reported renal lesions in 57% of TSC patients.⁴⁰ The principal manifestations include angiomyolipomas (85%), cysts

(45%), and renal malignant neoplasms (4%). Some of the malignant tumors originally thought to be renal cell carcinoma (RCC) are now regarded as malignant epithelioid angiomyolipomas.⁴¹ Other renal neoplasms, interstitial fibrosis with focal segmental glomerulosclerosis (FSGS), glomerular microhamartomas, and peripelvic and perirenal lymphangiomatous cysts have also been observed in TSC patients. Renal involvement in TSC often progresses insidiously but can result in considerable morbidity, including retroperitoneal hemorrhage, renal impairment (~1%), and death. Renal complications are the most frequent cause of death in TSC.³⁶

Renal Angiomyolipomas

Angiomyolipomas are hamartomatous structures composed of abnormal, thick-walled vessels and varying amounts of smooth muscle-like cells and adipose tissue (Fig. 45.10A, B). These are the most common renal lesion in TSC patients, evident in ~80% of TSC patients by age 10 years.³⁴ Whereas solitary angiomyolipomas are found in the general population, particularly among older women, TSC-associated angiomyolipomas are multiple and bilateral with a young age at onset. Angiomyolipomas rarely occur before 5 years of age but increase in frequency and size with age.⁴² These tumors can be locally invasive, extending into the perirenal fat or, more rarely, the collecting system, renal vein, and even the inferior vena cava and right atrium. Lymph node and splenic involvement probably represents multifocal origin rather than metastasis.

Clinical manifestations are due to hemorrhage (intratumoral or retroperitoneal) or mass effects (abdominal or flank masses and tenderness, hypertension, renal impairment). Women tend to have more numerous and larger angiomyolipomas than men. Pregnancy appears to increase the risk of rupture and hemorrhage.

Renal Cystic Disease

Renal cysts occur less frequently than angiomyolipoma in TSC patients (47% versus 80%⁴²). However, like angiomyolipomas, renal cysts tend to increase in size and number over time. The concurrence of cysts and angiomyolipomas, easily detected by CT, is strongly suggestive of TSC.

The cysts in TSC can develop from any nephron segment. When limited in number and size, TSC-related cysts are predominantly cortical. In some cases, glomerular cysts predominate. The epithelial lining of the cysts is distinctive and appears to be unique to TSC, with large and acidophilic epithelia containing large hyperchromatic nuclei with occasional mitotic

Figure 45.9 Facial angiofibromas in a 49-year-old patient with tuberous sclerosis complex.

Figure 45.10 Renal pathology in tuberous sclerosis complex. **A**, Cut section: multiple angiomyolipomas in the kidney of a 60-year-old symptomatic woman. **B**, Light microscopy: angiomyolipoma containing adipose tissue and spindle smooth muscle-like cells interspersed between abnormal vessels with thickened walls. (Hematoxylin and eosin; magnification $\times 16$.) **C**, Light microscopy: TSC cysts lined with distinctive epithelia consisting of large, acidophilic cells with hyperchromatic nuclei. (Hematoxylin and eosin; magnification $\times 65$.)

Clinical Diagnostic Criteria for Tuberous Sclerosis Complex (TSC)*

Major:

Facial angiofibromas or forehead plaque
 Nontraumatic ungual or periungual fibroma
 Hypomelanotic macules (>3)
 Shagreen patch (connective tissue nevus)
 Multiple retinal nodular hamartomas
 Cortical tubers
 Subependymal nodule
 Subependymal giant cell astrocytoma
 Cardiac rhabdomyomas (≥1)
 Lymphangioleiomyomatosis
 Renal angiomyolipoma

Minor:

Multiple, random dental pits
 Hamartomatous gastrointestinal or rectal polyps
 Bone cysts
 White matter radial migration lines
 Gingival fibromas
 Nonrenal hamartoma
 Retinal achromic patch
 “Confetti” skin lesions
 Multiple renal cysts

Figure 45.11 Clinical diagnostic criteria for tuberous sclerosis complex (TSC). *Two major features or one major feature with two minor features indicates definite TSC; one major feature and one minor feature indicate probable TSC; and one major feature or two minor features indicate possible TSC. (Modified with permission from reference 39.)

figures (Fig. 45.10C). Associated papillary hyperplasia and adenomas are common.

A small subset of affected infants can present with massive renal cystic disease reminiscent of ADPKD, severe hypertension, and a progressive decline in renal function with the onset of ESRD in the second or third decade of life. The majority of these patients have a contiguous germline deletion involving both the *TSC2* and *PKD1* genes, the PKTS contiguous gene syndrome (MIM 600273).⁴³ Early detection, strict blood pressure control, and prompt therapy for the associated infantile spasms may have a favorable impact on the overall prognosis.

Renal Neoplasms

Many cases of benign epithelial tumors, such as papillary adenomas and oncocytomas, have been reported in TSC patients. However, despite the multiplicity of benign tumors, neoplastic transformation is rare.⁴⁴

TSC-associated renal neoplasms are primarily clear cell RCC, but there is pathologic heterogeneity, with papillary and chromophobe carcinomas reported.⁴¹ The prognosis of TSC-associated renal carcinomas compared with sporadic renal carcinomas in the general population is unknown. The lifetime risk for development of RCC in the context of TSC is 2% to 3%.⁴⁴

Diagnosis

TSC is a pleiotropic disease in which the size, number, and location of the lesions can be variable, even among members of the same family. Major and minor criteria (Fig. 45.11) have been developed to guide the diagnostic approach in TSC. The diagnosis is made when two major features or one major and two minor ones can be demonstrated.³⁹ Imaging is the mainstay for

Figure 45.12 Radiologic findings associated with tuberous sclerosis complex. Contrast-enhanced CT scan showing bilateral angiomyolipomas in a 34-year-old symptomatic woman.

diagnosis of TSC-associated renal lesions. The presence of small cysts and fat-containing angiomyolipomas is strongly suggestive of TSC. Whereas the median age at presentation for both renal cysts and angiomyolipomas is 9 years, these lesions have been detected in patients as young as 16 days and 4 months, respectively.⁴²

Annual renal imaging is advised for TSC patients. Ultrasound may be more sensitive than CT for detection of small angiomyolipomas because fatty tissue is highly echogenic. Conversely, CT may be superior for detection of small angiomyolipomas in diffusely hyperechoic kidneys and for differentiation of small angiomyolipomas from perinephric or renal sinus fat (Fig. 45.12). On occasion, the distinction between an angiomyolipoma and carcinoma cannot be reliably established by imaging, and biopsy is indicated.

TSC-associated renal cysts can radiologically mimic simple cysts and, when numerous, ADPKD. In the absence of angiomyolipomas, TSC-related renal cystic disease is suggested by the limited number of cysts compared with ADPKD and the absence of associated hepatic cysts. Although 10% of TSC patients have hepatic angiomyolipomas, hepatic cysts are rare.

Gene-based diagnosis is currently available for *TSC1*- and *TSC2*-related disease as well as to detect large-scale deletions associated with the PKTS contiguous gene syndrome (<http://www.genetests.org/>).

Treatment

Renal Angiomyolipomas

Renal angiomyolipomas are benign lesions and often require no treatment. However, given the potential for growth and associated complications, such as pain, bleeding, and hypertension, annual re-evaluation with ultrasound or CT is recommended. Larger angiomyolipomas frequently develop microaneurysms and macroaneurysms, and the risk of serious hemorrhage correlates with aneurysms of more than 5 mm in diameter.³⁶ Therefore, these large angiomyolipomas require preemptive treatment with either surgical removal in a nephron-sparing procedure or embolization.³⁴ In addition to size and complications such as pain and hemorrhage, the inability to exclude an associated renal carcinoma is an indication for intervention. When an associated malignant neoplasm cannot be excluded, renal-sparing surgery, such as enucleation or partial nephrectomy, is preferred.

The increased frequency and size of the angiomyolipomas in women and the reports of hemorrhagic complications during pregnancy suggest that female sex hormones may accelerate the growth of these lesions. Therefore, it is prudent to caution patients with multiple angiomyolipomas about the potential risks of pregnancy and estrogen administration.

As noted, defective mTORC1 signaling is a central feature of TSC. A small clinical trial of sirolimus (rapamycin), an mTOR inhibitor, has demonstrated regression of astrocytomas, angiofibromas, and angiomyolipomas as well as improved pulmonary function in TSC patients.⁴⁵ The efficacy of everolimus, another mTOR inhibitor, is now being assessed in a clinical trial in TSC patients with angiomyolipomas (<http://clinicaltrials.gov>).

Renal Cystic Disease

The mainstay of treatment of the cystic disease associated with TSC is strict control of the hypertension. Surgical decompression of these cystic kidneys has been suggested, but no significant beneficial effect has been established.

Renal Carcinoma

Renal carcinoma should be suspected in enlarging, fat-poor lesions or when intratumoral calcifications are present. In these cases, biopsy is indicated. Because renal carcinoma is frequently bilateral in TSC, renal-sparing surgery should be performed whenever possible.

Transplantation

CKD, although rare in tuberous sclerosis, can occur by several different mechanisms, including angiomyolipoma-related parenchymal destruction, progressive renal cystic disease, interstitial fibrosis, and FSGS. A survey of 260 French dialysis centers indicated that the approximate prevalence of tuberous sclerosis-associated ESRD is 0.7 case per million and that of ESRD in tuberous sclerosis is 1 per 100.⁴⁶ CKD in tuberous sclerosis was more frequent in females (63%) and was diagnosed at a mean age of 29 years. Renal impairment was the first TSC manifestation in about half the cases. Renal tumors were frequent, with angiomyolipomas in 23%, cysts in 18%, and both in 54%, although malignant neoplasms were observed in only 14%. All but one of the 48 patients with ESRD were treated by dialysis; 20 were transplanted, with good results. Therefore, both dialysis and renal transplantation provide an adequate means of survival, but the risk of renal hemorrhage related to angiomyolipomas and malignant degeneration in TSC poses special problems. Therefore, it is advisable that patients with TSC and ESRD undergo bilateral nephrectomy when renal replacement therapy is initiated.

VON HIPPEL–LINDAU DISEASE

Definition

von Hippel–Lindau disease (VHL) is a dominantly transmitted, multisystem cancer predisposition syndrome associated with tumors of the eyes, cerebellum, spinal cord, adrenal glands, pancreas, and epididymis as well as renal and pancreatic cysts.⁴⁷

Genetic Basis of von Hippel–Lindau Disease

VHL results from germline mutations in the *VHL* tumor-suppressor gene. In approximately 80% of patients, VHL is

familial, and disease in ~20% of cases results from *de novo* mutations. Moreover, *VHL* mutations have been identified in the germline of VHL patients as well as in sporadic clear cell RCCs, implying that *VHL* plays an important role in the pathogenesis of clear cell RCC.

The VHL protein (pVHL) plays a critical role as a negative regulator of hypoxia-inducible genes.^{36,48} In the normal physiologic state, pVHL functions in a multiprotein complex that directs the α subunits of the transcription factor hypoxia-inducible factor (HIF- α) for destruction through the ubiquitination pathway. In cells that lack pVHL, HIF- α subunits are stabilized and bind to HIF- β family member proteins. The heterodimer then translocates to the nucleus, leading to overexpression of HIF target genes, which encode proteins that regulate glucose uptake, metabolism, extracellular pH, angiogenesis (vascular endothelial growth factor and platelet-derived growth factor B), and mitogenesis (transforming growth factor β and erythropoietin). This transcriptional dysregulation promotes the pathologic growth and survival of endothelial cells, pericytes, and stromal cells and ultimately their malignant transformation.^{47,48}

Clinical Manifestations

VHL has an incidence of 1 in 36,000 newborns and has been observed in all ethnic groups.⁴⁷ Biallelic *VHL* inactivation leads to increased risk of central nervous system (CNS) and retinal hemangioblastomas, clear cell RCCs, pheochromocytomas, pancreatic islet cell tumors, endolymphatic sac tumors, and papillary cystadenomas of the broad ligament (females) and epididymis (males). In addition, cystic changes can occur in the kidney and pancreas.⁴⁸

VHL-associated disease appears to cluster into two disease complexes (Fig. 45.13). In the initial stratification, VHL patients can be subclassified on the basis of a low risk (type 1) or high risk (type 2) for development of pheochromocytoma. Type 2 patients can be further subtyped according to the risk for development of RCC—low in type 2A and high in type 2B. In type 2C, patients present with familial pheochromocytoma without the other VHL-associated malignant neoplasms. Deletions and protein-truncating mutations are associated with the VHL type

Classification of VHL Based on Tumor Spectrum	
VHL Subtype	Tumor Manifestations
Type 1	Hemangioblastoma (CNS, retina), renal cell carcinoma Low risk for pheochromocytoma and pancreatic endocrine tumors
Type 2A	Hemangioblastoma (CNS, retina), pheochromocytoma, pancreatic endocrine tumors Low risk for renal cell carcinoma
Type 2B	Hemangioblastoma (CNS, retina), renal cell carcinoma, pheochromocytoma, pancreatic endocrine tumors
Type 2C	Predominantly pheochromocytoma Very limited risks for hemangioblastoma and renal cell carcinoma

Figure 45.13 Classification of VHL based on tumor spectrum. CNS, central nervous system. (Modified with permission from reference 48.)

1 phenotype, whereas type 2 disease primarily involves missense mutations.^{47,48}

RCCs are typically multiple and bilateral. Whereas RCC may present with hematuria or back pain, more often detection occurs as an incidental finding on unrelated imaging studies or when VHL families are screened for occult renal disease. The mean age at presentation is 35 to 40 years, although patients have been diagnosed in adolescence. In VHL, men and women are equally affected with RCC, in contrast to the male predominance in sporadic RCC. VHL-associated RCC metastasizes to the lymph nodes, liver, lungs, and bones and accounts for about 50% of VHL deaths.

In VHL, renal cysts arise from tubular cells that have undergone somatic loss of the wild-type allele. Renal cysts occur in about 60% of patients and are commonly bilateral; deterioration of renal function due to cystic kidney disease has been reported but is exceptional. However, some of these cysts become malignant over time, presumably because of mutations affecting other loci.³⁶

Pathology

RCC is one of the most common tumors in VHL, occurring in up to 75% of patients by age 60 years.⁴⁷ VHL-associated RCCs are mostly of the clear cell type and usually bilateral and multifocal in distribution. Detailed microscopic examination of VHL-associated renal cystic lesions often reveals small foci of carcinoma; these RCCs tend to have low-grade histology and a better 10-year survival than sporadic RCC. More advanced RCCs do metastasize, and metastatic disease is a major cause of death in VHL patients.

Diagnosis

The minimal clinical criteria for the diagnosis of VHL in an at-risk individual include the presence of a single retinal or cerebellar hemangioblastoma, or RCC, or pheochromocytoma. As many as 50% of affected family members may manifest only one feature of the syndrome. In presumed sporadic cases, the clinical diagnosis requires two or more retinal or CNS hemangioblastomas or a single hemangioblastoma and a characteristic visceral tumor.

Molecular analysis of the VHL gene is indicated in patients with known or suspected VHL or in at-risk children from VHL families, given that unsuspected, untreated tumors can cause significant morbidity.⁴⁷ Presymptomatic genotyping can be useful in determining the phenotypic classification of VHL and be used to direct monitoring for a specific subset of tumors. In addition, genotyping can be useful in distinguishing whether a pheochromocytoma has occurred in the context of VHL type 2 or in multiple endocrine neoplasia type 2 or is nonsyndromic.^{47,48} Genetic testing information is available at <http://www.genetests.org/>.

In proven gene carriers or those at-risk individuals who cannot be evaluated at the molecular level, regular surveillance for occult disease manifestations is indicated. A comprehensive screening program, typically initiated at age 18 years and performed annually, includes gadolinium-enhanced magnetic resonance imaging (MRI) of the brain and spinal cord, detailed ophthalmologic examination, and a CT or MRI scan of the abdomen and pelvis to screen for visceral manifestations.³⁶ About 40% of patients with VHL develop radiographically apparent renal cancers, which may appear as simple or complex cysts or solid renal masses. Comparison of images before and after the

administration of contrast material distinguishes whether lesions are enhancing. Ultrasound can be helpful in the further characterization of indeterminate renal lesions but should not be the primary mode of diagnostic imaging. For individuals with VHL type 2 mutations, annual surveillance for pheochromocytoma should include a 24-hour urine collection for metanephrines and catecholamines, abdominal magnetic resonance tomography, or *m*-iodobenzylguanidine (MIBG) scintigraphy.⁴⁷

Germline mutations in the VHL gene have been detected in some families who do not meet the clinical criteria for VHL. Such families should be considered to have VHL and be managed like typical VHL families, including periodic clinical screening. For those at-risk individuals who do not inherit the mutant gene, further clinical surveillance is not necessary.

Differential Diagnosis

The differential diagnosis of VHL-associated renal lesions includes several conditions, most notably ADPKD and TSC (Fig. 45.14). Like VHL, ADPKD affects both sexes with a similar mean age at presentation. However, kidney involvement in VHL is characterized by a few bilateral cysts (Fig. 45.15A), RCC, normal kidney size, normal blood pressure, and usually normal renal function. Cyst infection, a frequent finding in ADPKD, is uncommon in VHL. RCC is an infrequent complication of ADPKD. Cysts in the liver are frequent in ADPKD and rare in VHL. Pancreatic cysts are rare in ADPKD but can be numerous and scattered through the pancreas in VHL (Fig. 45.15A). The CNS in ADPKD is affected by arterial aneurysms, whereas hemangioblastomas are the CNS manifestation of VHL (Fig. 45.15B).

TSC should be considered in the differential diagnosis of multiple renal tumors. In both TSC and VHL, multiple renal cysts occur. However, the TSC-associated renal tumor is usually an angiomyolipoma, and extrarenal lesions readily distinguish VHL and TSC.

Treatment

At present, surgery is the mainstay for RCC therapy in VHL patients. Optimal management requires surgical intervention before renal vein invasion and distant metastases occur because metastatic lesions respond poorly to chemotherapy and radiation therapy. Nephron-sparing surgery is the procedure of choice when possible. Repeated surgical intervention may be required as tumors continue to develop. Laparoscopic surgery may have a role in the future management of these patients.

Bilateral nephrectomy and renal transplantation may be an acceptable alternative to repeated nephron-sparing surgery in patients with VHL-associated RCC. It remains to be determined whether post-transplantation immunosuppression enhances the growth of the retinal and CNS hemangioblastomas and other lesions found in patients with VHL.

In terms of medical management, drugs that inhibit HIF- α , or its downstream targets, could be therapeutically useful in pVHL-related hemangioblastomas and clear cell RCCs.⁴⁸ Whereas DNA-binding transcription factors such as HIF have not proved to be tractable as drug targets *per se*, agents such as mTOR inhibitors that downregulate HIF- α protein levels are attractive as therapeutic agents; preclinical studies indicate that pVHL-defective cells are quite sensitive to mTOR inhibitors. Antibodies directed against vascular endothelial growth factor have shown significant efficacy in RCC in terms of tumor

Clinical and Genetic Features of Adult Renal Cystic Disease						
	Simple Cysts	ADPKD	MSK	VHL	TSC	Acquired Cystic Disease

shrinkage and disease stabilization.⁴⁸ A number of clinical trials are in progress (<http://clinicaltrials.gov>).

SIMPLE CYSTS

Definition

Simple renal cysts are the most commonly acquired renal cystic lesion and occur twice as frequently in men as in women. Simple cysts are usually unilateral and may be either solitary or multiple. They occur rarely in children but become increasingly common with age.⁴⁹ In one large ultrasound study, unilateral cysts were detected in 1.7% of patients 30 to 49 years of age, 11% of patients 50 to 70 years of age, and 22% to 30% of patients older than 70 years.⁵⁰ This age-related increase in cyst incidence has been corroborated by MR studies.⁵¹

Etiology and Pathogenesis

Simple renal cysts likely originate from the distal convoluted tubule or collecting ducts and may arise from renal tubular diverticula, but the pathogenic mechanism is unknown. Focal tubular obstruction and renal parenchymal ischemia have both been suggested as etiologic processes. Less likely is the possibility that simple cysts arise from calyceal diverticula because simple cysts are often found in the renal cortex and their frequency increases with age.

In addition to age, smoking, renal dysfunction, and hypertension⁵² have been implicated as risk factors in the occurrence of simple cysts. However, these associations may be coincidental, given that the studies were largely retrospective, the cohorts had variable reasons for diagnostic referral, and the observations were not optimally controlled for age of the patient.⁴⁹

Clinical Manifestations

Simple cysts are typically asymptomatic. On occasion, patients present with hypertension, hematuria, abdominal or back pain due to bleeding, palpable abdominal mass, evidence of infection, or obstruction of the collecting system. Clinical symptoms are more common with neoplasms than with simple cysts. Therefore, the onset of symptoms should raise the possibility of an associated malignant neoplasm and prompt additional diagnostic studies.^{49,53}

Pathology

Whether unilateral or bilateral, simple cysts are usually spherical and unilocular. They may be solitary or multiple. On average, simple cysts measure 0.5 to 1.0 cm in diameter, but 3- to 4-cm cysts are not uncommon. Simple cysts can occur in the cortex (where they often protrude from the cortical surface), the corticomedullary junction, or the medulla. By definition, they do not communicate with the renal pelvis. The cyst walls are typically thin and transparent, lined with a single layer of flattened epithelium. Cyst fluid is essentially an ultrafiltrate of plasma. In the wake of infection, cyst walls can become thickened, fibrotic, and even calcified.

Diagnosis

Simple cysts are most often detected as incidental findings during abdominal imaging studies. They are occasionally discovered

during radiologic evaluation of palpable abdominal masses, pyelonephritis, or hematuria following abdominal trauma.

The critical clinical issue is to distinguish single or multiple simple cysts from cysts associated with ADPKD, other cystic diseases, or RCC. This distinction can usually be made on the basis of the patient's age, family history, and renal imaging patterns.^{49,54}

The ultrasound features of simple cysts include smooth walls, no septa, and no intracystic debris. If the ultrasound pattern is indeterminate, CT scanning should be performed. A classification system for renal cysts based on their appearance and enhancement on CT, described by Bosniak, is widely used (see Fig. 59.11).⁵⁴ Benign cysts (class I) have homogeneous attenuation, no contrast enhancement, thin and smooth cyst walls, and no associated calcifications unless prior infection has occurred.

Treatment

Simple cysts associated with pain or renin-dependent hypertension can be punctured with ultrasound guidance and drained, and a sclerosing agent is instilled into the cyst cavity. Laparoscopic or retroperitoneoscopic cyst unroofing may be more appropriate for large cysts containing volumes in excess of 100 ml. Infection with Enterobacteriaceae, staphylococci, and *Proteus* has been reported in simple cysts, and operative or percutaneous drainage is often required in addition to antibiotic treatment.

SOLITARY MULTILOCULAR CYSTS

Solitary multilocular cysts are generally benign neoplasms that arise from the metanephric blastema.⁵⁵ These solitary cysts have also been designated multilocular cystic nephroma, benign cystic nephroma, and papillary cystadenoma. By definition, the cystic structures are unilateral, solitary, and multilocular. The cystic locules do not communicate with each other or with the renal pelvis. These locules are lined with a simple epithelium, and the interlocular septa do not contain differentiated renal epithelia structures.

Multilocular cysts represent a spectrum⁵⁶; at one end is cystic nephroma, and at the other end is cystic partially differentiated nephroblastoma (CPDN), in which the septa contain foci of blastemal cells. It is not certain whether a multilocular cyst represents a congenital abnormality in nephrogenesis, a hamartoma, a partially or completely differentiated Wilms' tumor, or a benign variant of Wilms' tumor.

A bimodal age distribution has been described⁵⁵; approximately half the cases occur in children younger than 4 years, and half the cases are detected in adults. The childhood cases (mostly CPDN) are usually found in boys, whereas multilocular cysts presenting in adulthood (mostly cystic nephroma) occur more commonly in women. An abdominal or flank mass is the most common clinical feature, as these cysts are typically quite large and often replace an entire pole. Associated hematuria, calculi, urinary tract obstruction, and infection occur in rare instances. Diagnosis can be made by either ultrasound or CT (Fig. 45.16).

Almost all multilocular cysts are Bosniak class III (see Fig. 59.11), complex renal cysts suggestive of malignancy.⁵⁴ CPDN in children may contain blastema and incompletely differentiated metanephric tissue but usually has a benign course.⁵⁷ In adults, associated foci of RCC or sarcoma must be excluded; partial nephrectomy is usually required. However, the typical prognosis of solitary multilocular cysts is excellent.

Figure 45.16 Solitary multilocular cyst. Contrast-enhanced CT image shows a solitary, septated, and well-circumscribed renal cystic lesion in the right kidney.

RENAL LYMPHANGIOMATOSIS

Renal lymphangiomatosis is a rare, generally benign disorder characterized by developmental malformation of renal lymphatic channels.⁵⁸ It has also been referred to as hilar, pericalyceal, paracalyceal, peripelvic, or parapelvic lymphangiectasis.

The cystic phenotype is widely variable and the underlying pathogenesis is unclear. The dilation may involve a single lymphatic channel or multiple channels. The lymphangiectasis may be unilateral or bilateral, may be limited to the hilar region, or may extend into the renal parenchyma to the corticomedullary junction. On occasion, renal lymphangiomatosis may be very extensive and simulate ADPKD. The thin-walled cysts are lined by lymphatic endothelium, and the cyst fluid is quite distinct from that in ADPKD cysts as it contains lymphatic constituents such as albumin and lipid.

The characteristic ultrasound or CT findings include multiple, bilateral small peripelvic cysts that splay the renal hilum as well as capsular cysts in the perirenal space, both separated by thin septations.⁵⁹ Renal lymphangiomatosis is most often asymptomatic and require no treatment. However, the condition may be exacerbated by pregnancy, resulting in large perinephric lymph collections and ascites that may require percutaneous drainage.⁶⁰

GLOMERULOCYSTIC KIDNEY DISEASE

Cystic glomeruli are evident in three different clinical contexts: (1) isolated glomerulocystic kidney disease (GCKD); (2) glomerulocystic kidneys associated with heritable malformation syndromes, such as tuberous sclerosis, Meckel syndrome, medullary cystic kidney disease, orofaciocigital syndrome type I, trisomy 9, trisomy 13, trisomy 18, the short-rib polydactyly syndromes, and Zellweger cerebrohepatorenal syndrome; and (3) glomerular cysts present in dysplastic kidneys.⁶¹

GCKD can occur as a sporadic condition, a familial disorder, or the infantile manifestation of ADPKD. On pathologic examination, the kidney architecture is normal, with no dysplastic elements in the cortex and no evidence of urinary tract obstruction. Cystic dilation predominantly involves Bowman's space and the initial proximal tubule; it is defined as a twofold to threefold dilation of Bowman's space versus the normal glomerular dimension.⁶¹ Glomerular cysts can be distributed from the subcapsular

zone to the inner cortex. The typical ultrasound pattern in GCKD involves increased echogenicity of the renal cortex with minute cysts, smaller than those evident in ADPKD. Young infants with either familial or sporadic forms of GCKD may also have renal medullary dysplasia and biliary dysgenesis.⁶¹

GCKD is usually transmitted as an autosomal dominant trait. It is usually discovered in infants with a familial history of ADPKD. In these infants, the kidneys are bilaterally enlarged and diffusely cystic. In addition, familial GCKD has been observed in infants, older children, and adults in whom the disease locus is not linked to *PKD1* or *PKD2*, but the specific causative gene has yet to be identified.⁶² In these non-ADPKD-associated GCKD families, the kidneys are typically normal in size, although enlarged kidneys are occasionally observed. Finally, several sporadic cases of nonsyndromal GCKD have been described, suggesting either new spontaneous mutations or a recessively transmitted disorder.⁶³

Familial hypoplastic GCKD (MIM 137920) is probably a different type of GCKD. The kidneys are smaller than normal and often associated with medullocalyceal abnormalities. The disease is pleiotropic among affected family members with variable associations of hypoplastic GCKD, gynecologic abnormalities, and maturity-onset diabetes of the young, type 5, which results from mutations in *TCF2*, the gene encoding hepatocyte nuclear factor 1 β .⁶⁴

ACQUIRED CYSTIC DISEASE

Hypokalemic Cystic Disease

Renal cysts are often seen in association with chronic hypokalemia due to primary hyperaldosteronism or other renal potassium-wasting disorders. Nearly 50% of patients with idiopathic adrenal hyperplasia and 60% of patients with adrenal tumors have been found to have renal cysts, which were distributed primarily in the renal medulla. These cysts typically regress after adrenalectomy.⁶⁵

Hilar Cysts

Hilar cysts are spherical accumulations of clear, fat droplet-containing fluid within the renal sinus. These cystic structures are not lined by epithelia. They are most commonly seen in debilitated patients and may represent atrophy of the renal sinus fat.

Perinephric Pseudocysts

Perinephric pseudocysts are also unlined cavities. They typically occur under the renal capsule or in the perirenal fascia as a result of urine extravasation from a renal cyst after traumatic or spontaneous rupture or as the posterior extension of a pancreatic pseudocyst. Surgical intervention is indicated for associated urinary tract obstruction. Otherwise, treatment is directed to the underlying cause.

ACQUIRED CYSTIC DISEASE IN RENAL FAILURE

Acquired cystic disease is a significant complication of prolonged renal failure. It should be considered in the differential diagnosis of cystic disease presenting with long-standing chronic renal failure (see Fig. 45.14). Acquired cystic disease is discussed further in Chapter 85.

Alport's and Other Familial Glomerular Syndromes

Clifford E. Kashtan

ALPORT'S SYNDROME

Definition

Alport's syndrome (AS) is a generalized, inherited disorder of basement membranes due to mutations affecting specific proteins of the type IV (basement membrane) collagen family. The major features of AS are hematuria, progressive nephritis with proteinuria and declining renal function, sensorineural deafness, and ocular abnormalities. The course of AS is gender dependent; affected males typically have severe disease, whereas the manifestations of AS in women are usually mild. In 1902, Guthrie provided the first description of familial hematuria.¹ Later studies of Guthrie's family by Hurst² and Alport³ revealed the progressive nature of the nephropathy, its association with deafness, and the poorer prognosis in affected males. In the 1970s, the glomerular basement membrane (GBM) was recognized as the site of the primary abnormality in AS.^{4,6} Indirect evidence of abnormalities in type IV collagen^{7,8} was followed by mapping of the major AS locus to the X chromosome,⁹ cloning of a new type IV collagen gene (*COL4A5*) and its assignment to the same X-chromosomal region,¹⁰ and identification of the first *COL4A5* mutations in patients with X-linked AS.¹¹

Etiology and Pathogenesis

Type IV Collagen

Type IV collagen is a major constituent of basement membranes. The type IV collagen family of proteins comprises six isomeric chains, designated $\alpha 1(\text{IV})$ to $\alpha 6(\text{IV})$. Each of these chains has a major collagenous domain of about 1400 residues containing the repetitive triplet sequence glycine (Gly)-X-Y, in which X and Y represent a variety of other amino acids; a C-terminal noncollagenous (NC1) domain of about 230 residues; and a noncollagenous N-terminal sequence of 15 to 20 residues.

Each type IV collagen molecule is a heterotrimer composed of three α chains. Formation of these heterotrimers is initiated by C-terminal NC1 domain interactions, accompanied by folding of the collagenous domains into triple helices. There is evidence for at least three types of type IV collagen heterotrimer: $\alpha 1(\text{IV})_2\text{-}\alpha 2(\text{IV})$, $\alpha 3(\text{IV})\text{-}\alpha 4(\text{IV})\text{-}\alpha 5(\text{IV})$, and $\alpha 5(\text{IV})_2\text{-}\alpha 6(\text{IV})$. Type IV collagen triple helices form open, nonfibrillar networks that associate with laminin assemblies through interactions mediated by nidogen to form basement membranes.

The six type IV collagen genes are arranged in pairs on three chromosomes (Fig. 46.1). The 5' ends of each gene pair are adjacent to each other, separated by sequences of varying length that contain motifs involved in the regulation of transcriptional activity.

Tissue Distribution of Type IV Collagen There are several distinct type IV collagen networks in basement membranes: a ubiquitous network comprising the $\alpha 1(\text{IV})$ and $\alpha 2(\text{IV})$ chains; and other networks, restricted in distribution, composed of $\alpha 3(\text{IV})$, $\alpha 4(\text{IV})$, and $\alpha 5(\text{IV})$ chains, or $\alpha 5(\text{IV})$ and $\alpha 6(\text{IV})$ chains. GBM contains separate $\alpha 1\text{-}\alpha 2(\text{IV})$ and $\alpha 3\text{-}\alpha 4\text{-}\alpha 5(\text{IV})$ networks, whereas epidermal basement membranes contain separate networks of $\alpha 1\text{-}\alpha 2(\text{IV})$ chains and $\alpha 5\text{-}\alpha 6(\text{IV})$ chains. It is likely that these networks have different functional characteristics and interact differently with other matrix components and with adjacent cells.

Genetics

Three forms of AS have been established on a molecular genetic basis: an X-linked form resulting from mutations at the *COL4A5* locus, primarily affecting the $\alpha 5(\text{IV})$ chain; an autosomal recessive form arising from mutations at the *COL4A3* locus or the *COL4A4* locus, affecting the $\alpha 3(\text{IV})$ and $\alpha 4(\text{IV})$ chains, respectively; and an autosomal dominant form due to heterozygous mutations in *COL4A3* or *COL4A4* (Fig. 46.2).

X-Linked Alport's Syndrome X-linked Alport's syndrome (XLAS) is the predominant form of the disease, accounting for about 80% of patients. Several hundred *COL4A5* mutations have been described, mostly missense mutations, splice-site mutations, and deletions of fewer than 10 base pairs.^{12,13} A common missense mutation involves replacement of a glycine residue in the collagenous domain of the $\alpha 5(\text{IV})$ chain by another amino acid. Such mutations are thought to interfere with the normal folding of the $\alpha 5(\text{IV})$ chain into triple helices with other $\alpha(\text{IV})$ chains.

Male patients with *COL4A5* deletions consistently progress to end-stage renal disease (ESRD) during the second or third decade of life and have deafness¹⁴; this phenotype is associated with most of the missense, nonsense, and splicing mutations of *COL4A5* described so far. Several missense mutations of *COL4A5* have been associated with late-onset (after the third decade) ESRD and with late development of deafness or normal hearing. The severity of disease in a female heterozygous for a *COL4A5* mutation probably depends primarily on the relative activities of the mutant and normal X chromosomes in renal, cochlear, and ocular tissues.

Autosomal Recessive Alport's Syndrome Autosomal recessive Alport's syndrome (ARAS) arises from mutations affecting both alleles of *COL4A3* or *COL4A4*.^{15,16} ARAS should be suspected when an individual exhibits the typical clinical and pathologic features of the disease but lacks a positive family history, especially when a young female has findings indicative of severe

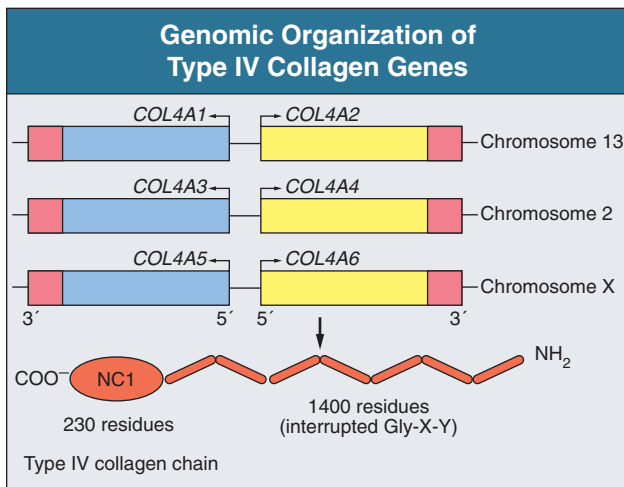

Figure 46.1 Genomic organization of type IV collagen genes.

Molecular Genetics of Alport's Syndrome		
Inheritance	Affected Locus	Gene Product
X-linked (XLAS)	<i>COL4A5</i>	$\alpha 5(\text{IV})$
X-linked + leiomyomatosis	<i>COL4A5</i> + <i>COL4A6</i>	$\alpha 5(\text{IV})$ + $\alpha 6(\text{IV})$
Autosomal recessive (ARAS)	<i>COL4A3</i> <i>COL4A4</i>	$\alpha 3(\text{IV})$ $\alpha 4(\text{IV})$
Autosomal dominant	<i>COL4A3</i> <i>COL4A4</i>	$\alpha 3(\text{IV})$ $\alpha 4(\text{IV})$

Figure 46.2 Molecular genetics of Alport's syndrome.

disease, such as deafness, nephrotic syndrome, and impaired renal function. However, sporadic cases of AS may represent *de novo* mutations at the *COL4A5* locus or a germline *COL4A5* mutation in the proband's mother. Most patients with ARAS develop ESRD and deafness before the age of 30 years, regardless of gender.

Autosomal Dominant Alport's Syndrome Heterozygous mutations in *COL4A3* or *COL4A4* typically result in asymptomatic hematuria^{15,16} but in some families may also be associated with progressive nephropathy, that is, autosomal dominant Alport's syndrome (ADAS).^{17,18} ADAS patients tend to have a slower course to ESRD than do those with XLAS or ARAS.¹⁹

Type IV Collagen in Alport's Basement Membranes

The GBMs and tubular basement membranes of males with XLAS usually fail to stain for the $\alpha 3(\text{IV})$, $\alpha 4(\text{IV})$, and $\alpha 5(\text{IV})$ chains but do express the $\alpha 1(\text{IV})$ and $\alpha 2(\text{IV})$ chains (Fig. 46.3).²⁰ Women with XLAS frequently exhibit mosaicism of GBM expression of the $\alpha 3(\text{IV})$, $\alpha 4(\text{IV})$, and $\alpha 5(\text{IV})$ chains, whereas expression of the $\alpha 1(\text{IV})$ and $\alpha 2(\text{IV})$ chains is preserved (see Fig. 46.3). Most males with XLAS show no epidermal basement membrane expression of $\alpha 5(\text{IV})$, whereas female heterozygotes frequently display mosaicism (Fig. 46.4). Lens capsules of some males with XLAS do not express the $\alpha 3(\text{IV})$, $\alpha 4(\text{IV})$, or $\alpha 5(\text{IV})$ chains, whereas expression of these chains appears normal in other patients.

In most patients with ARAS, GBM shows no expression of the $\alpha 3(\text{IV})$, $\alpha 4(\text{IV})$, or $\alpha 5(\text{IV})$ chains, but $\alpha 5(\text{IV})$ and $\alpha 6(\text{IV})$

are expressed in Bowman's capsule, distal tubular basement membrane, and epidermal basement membrane (Fig. 46.5).²⁰ Therefore, XLAS and ARAS may be differentiated by immunohistochemical analysis. Basement membrane expression of type IV collagen α chains appears to be normal in patients with ADAS.

These observations indicate that a mutation affecting one of the chains involved in the $\alpha 3$ – $\alpha 4$ – $\alpha 5(\text{IV})$ network can prevent GBM expression not only of that chain but also of the other two chains. Most observational and experimental evidence supports the hypothesis that these effects reflect post-translational events. Some mutant chains are unable to participate in the formation of trimers; as a result, the normal chains that are prevented from forming trimers undergo degradation. Other mutations may allow formation of abnormal trimers that are degraded before deposition in basement membranes can occur.

Clinical Manifestations

Renal Defects

Hematuria is the cardinal finding of AS. Affected males have persistent microscopic hematuria. Many also have episodic gross hematuria, precipitated by upper respiratory infections, usually during the first two decades of life. Hematuria has been discovered in the first year of life in affected boys, in whom it is probably present from birth. Boys who are free of hematuria during the first 10 years of life are unlikely to be affected.

More than 90% of females with XLAS have persistent or intermittent microscopic hematuria, but about 7% of obligate heterozygotes never manifest hematuria.²¹ Hematuria appears to be persistent in both males and females with ARAS. About 50% of carriers of *COL4A3* or *COL4A4* mutations have hematuria.^{15,16}

Proteinuria is usually absent early in life but develops eventually in all males with XLAS and in both males and females with ARAS. Proteinuria increases progressively with age and may result in the nephrotic syndrome. Proteinuria develops eventually in most heterozygous females.²¹ Hypertension also increases in incidence and severity with age. Similar to proteinuria, hypertension is more likely to occur in affected males than in affected females with XLAS, but there are no gender differences in the hypertension frequency in ARAS.

ESRD develops in all affected males with XLAS, at a rate determined primarily by the nature of the underlying *COL4A5* mutation.¹⁴ Thus, the rate of progression is fairly constant among affected males within a particular family, but there is significant interkindred variability. Significant intrakindred variability in the rate of progression to ESRD has been reported in some families with missense *COL4A5* mutations.

Progression to ESRD in females with XLAS was, until recently, considered an unusual event. However, a study of several hundred XLAS females found that 12% developed ESRD before the age of 40 years (compared with 90% of XLAS males), increasing to 30% by age 60 years and 40% by age 80 years.²¹ The risk for ESRD was significantly increased in heterozygotes with proteinuria. The outcome of XLAS in females is presumed to be dependent on the relative activities of the normal and mutant X chromosomes, but this has yet to be proved. Gross hematuria in childhood, nephrotic syndrome, and the finding of diffuse GBM thickening by electron microscopy are risk factors for chronic kidney disease in affected females.²² Sensorineural deafness and anterior lenticonus are also indicative of an unfavorable outcome in affected women. Both males and females with

Figure 46.3 Immunohistochemistry of glomerular basement membrane (GBM) in X-linked Alport's syndrome. In a normal individual, GBM stains strongly for the $\alpha 3(\text{IV})$, $\alpha 4(\text{IV})$, and $\alpha 5(\text{IV})$ chains of type IV collagen. Staining of GBM of an affected male is negative for each of these chains, whereas an affected female shows mosaic immunoreactivity.

ARAS appear likely to progress to ESRD during the second or third decade of life.

Cochlear Defects

Deafness is frequently but not universally associated with the Alport's renal lesion, occurring in about 80% of males and 25% to 30% of females with the disease.^{14,21} In some families with Alport's nephropathy and apparently normal hearing, deafness may occur late and be very slowly progressive.

Hearing loss in AS is never congenital and usually becomes apparent by late childhood to early adolescence in boys with XLAS and in both boys and girls with ARAS. Hearing impairment in members of families with AS is always accompanied by evidence of renal involvement. There is no convincing evidence that deaf males lacking renal disease can transmit AS to their offspring. In its early stages, the hearing deficit is detectable only by audiometry, with bilateral reduction in sensitivity to tones in the range 2000 to 8000 Hz. In affected males, the deficit extends progressively to other frequencies, including those of conversational speech.

Ocular Defects

Ocular defects occur in 30% to 40% of XLAS males and in about 15% of XLAS females.^{14,21} Anterior lenticonus, which is virtually

pathognomonic of AS, occurs in about 15% of XLAS males and is almost entirely restricted to AS families with progression to ESRD before the age of 30 years and deafness.¹⁴ Anterior lenticonus is absent at birth, usually appearing during the second to third decade of life, and is bilateral in 75% of patients (Fig. 46.6A). The spectrum and frequencies of ocular lesions appear to be similar in XLAS and ARAS.²³

Another common ocular manifestation of AS is a maculopathy, which consists of whitish or yellowish flecks or granulations in a perimacular distribution (Fig. 46.6B) and occurs in 15% to 30% of patients. The maculopathy does not appear to be associated with any visual abnormalities.

Corneal endothelial vesicles (posterior polymorphous dystrophy) have been observed in AS and may indicate defects in Descemet's membrane, the basement membrane underlying the corneal endothelium. Recurrent corneal erosion in AS has been attributed to alterations of the corneal epithelial basement membrane.

Leiomyomatosis

The association of AS with leiomyomatosis of the esophagus and tracheobronchial tree has been reported in about 30 families.¹³ Affected females typically exhibit genital leiomyomas as well, with clitoral hypertrophy and variable involvement of the labia

Figure 46.4 Immunohistochemistry of epidermal basement membrane (EBM) in X-linked Alport's syndrome. **A**, In a normal male, EBM shows strong staining for $\alpha 5(\text{IV})$ at the dermoepidermal junction (arrows) between dermis (D) and epidermis (E). **B**, In an affected female, EBM shows mosaic staining (arrow); the bracket identifies a length of EBM negative for $\alpha 5(\text{IV})$. **C**, In affected males, staining of EBM (arrows) for $\alpha 5(\text{IV})$ is absent.

majora and uterus. Bilateral posterior subcapsular cataracts also occur frequently in affected individuals. Symptoms usually appear in late childhood and include dysphagia, postprandial vomiting, retrosternal or epigastric pain, recurrent bronchitis, dyspnea, cough, and stridor. All patients with AS–diffuse leiomyomatosis complex have been found to have deletions that encompass the 5' ends of *COL4A5* and *COL4A6*.

Hematologic Defects

An autosomal dominant syndrome of hereditary nephritis, deafness, and megathrombocytopenia, Epstein's syndrome, has been described in a handful of families. Families with Fechtner's syndrome exhibit these features as well as leukocyte inclusions (May-Hegglin anomaly). Both Epstein's and Fechtner's syndromes arise from mutations in non-muscle myosin heavy chain IIA.²⁴ Basement membranes of these patients do not exhibit abnormalities in expression of type IV collagen α chains. There-

fore, Epstein's and Fechtner's syndromes are best considered distinct forms of hereditary nephritis rather than variants of AS.

Pathology

There are no pathognomonic lesions by light microscopy or direct immunofluorescence in AS. Indirect immunofluorescence of type IV collagen α -chain expression in renal or skin basement membranes can be diagnostic (see earlier discussion) and is increasingly available in specialized laboratories around the world.

Electron microscopy frequently reveals diagnostic abnormalities. The cardinal fine structural feature of the kidney that occurs in most patients with AS is the variable thickening, thinning, basket weaving, and lamellation of the GBM (Fig. 46.7). The thick segments measure up to 1200 nm in depth, usually have irregular outer and inner contours, and are found more commonly in males than in females. The lamina densa is transformed into a heterogeneous network of membranous strands, which enclose clear electron-lucent areas that may contain round granules of variable density measuring 20 to 90 nm in diameter. There are variable degrees of epithelial foot process fusion.

Not all Alport's kindreds demonstrate these characteristic ultrastructural features. Thick, thin, normal, and nonspecifically altered GBM have all been described. Affected young males, heterozygous females at any age, and, on occasion, affected adult males may have diffusely attenuated GBM measuring as little as 100 nm or less in thickness rather than the pathognomonic lesion. Although diffuse attenuation of GBM has been considered the hallmark of thin basement membrane nephropathy (as discussed elsewhere in this chapter), some patients with this abnormality are members of kindreds with a history of progression to renal failure. Therefore, the significance of an ultrastructural finding of thin GBM must be considered in the context of the family history, basement membrane expression of type IV collagen α chains, and, if it is available, molecular genetic information.

Diagnosis and Differential Diagnosis

A summary of the evaluation of patients with hematuria and a positive family history is given in Figure 46.8. AS should be included in the initial differential diagnosis of patients with persistent microscopic hematuria, once structural abnormalities of the kidneys or urinary tract have been excluded. The presence on electron microscopy of diffuse thickening and multilamellation of the GBM predicts a progressive nephropathy, regardless of family history. However, in a patient with a negative family history, electron microscopy cannot differentiate *de novo* XLAS from ARAS. In some patients, the biopsy findings may be ambiguous, particularly in females and young patients of either sex. Furthermore, families with progressive nephritis and *COL4A5* mutations in association with GBM thinning have been described, indicating that the classic Alport's GBM lesion is not present in all Alport's kindreds.

It is not unusual to see a patient with hematuria and to discover that multiple relatives also have hematuria, although none has ever undergone kidney biopsy. Who should undergo biopsy in such instances? The natural history of the AS renal lesion suggests that older, male subjects are more likely to exhibit diagnostic ultrastructural GBM abnormalities. In families in which a firm diagnosis of AS has been established, evaluation of individuals with newly recognized hematuria can be limited to ultrasound

Figure 46.5 Immunohistochemistry of the kidney in a patient with autosomal recessive Alport's syndrome. **A**, Normal GBM and Bowman's capsule staining for $\alpha 3(\text{IV})$, $\alpha 4(\text{IV})$, and $\alpha 5(\text{IV})$. **B**, Patient shows no GBM staining, but it is present in Bowman's capsule (arrow) and distal tubular basement membranes (arrowheads).

of the kidneys and urinary tract to exclude coincidental tumor or structural anomalies of the urinary tract.

Absence of the $\alpha 3$, $\alpha 4$, and $\alpha 5$ chains of type IV collagen from GBM and distal tubular basement membrane has not been described in any condition other than AS, making this a diagnostic finding on kidney biopsy (Fig. 46.9). Examination of skin biopsy specimens by immunofluorescence for expression of

$\alpha 5(\text{IV})$ in the epidermal basement membrane may be informative, but apparently normal expression of type IV collagen α chains in basement membranes does not exclude the diagnosis of AS. Mosaic expression of $\alpha 5(\text{IV})$ is frequent in heterozygous females. Although mosaic expression of $\alpha 5(\text{IV})$ is diagnostic of the carrier state, a normal result does not exclude heterozygosity. A female member of an Alport's kindred who does not have

Figure 46.9 Immunostaining for type IV collagen in Alport's syndrome. *In some Alport's kindreds, staining of basement membranes for type IV collagen chains is entirely normal. Therefore, a normal result does not exclude a diagnosis of X-linked Alport's syndrome. †Some heterozygous females have normal basement membrane immunoreactivity for type IV collagen chains. Therefore, a normal result does not exclude the carrier state.

hematuria may still be a carrier but is less likely to exhibit detectable mosaicism than is a female with hematuria.

A firm histologic diagnosis of AS cannot always be established, or it may not be possible to determine the mode of transmission, despite careful evaluation of the pedigree and application of the full range of histologic methods. In these situations, genetic analysis may provide information essential for determining prognosis and guiding genetic counseling. Genetic analysis for AS is becoming increasingly available as a clinical assay in commercial laboratories.

Glomerular diseases that typically occur sporadically may on occasion be heritable and should be considered in the differential diagnosis. These include focal segmental glomerulosclerosis, membranous nephropathy, membranoproliferative glomerulonephritis, and IgA nephropathy.

Natural History

Microscopic hematuria, the first and invariable renal manifestation of AS, probably reflects GBM thinning and a tendency to develop focal ruptures because of defective expression of the $\alpha 3$ – $\alpha 4$ – $\alpha 5(\text{IV})$ network. Anterior lenticonus most likely results from the inability of the abnormal lens capsule to maintain the normal conformation of the lens. Ultrastructural studies of Alport's cochleae suggest that the hearing deficit may be attributable to a defect in adherence of the organ of Corti to the basilar membrane.²⁵

AS in its early stages is clinically and often histologically indistinguishable from thin basement membrane nephropathy, which typically has a benign outcome. GBM attenuation is therefore an insufficient explanation for the divergent natural histories of the two conditions. What factors initiate and drive the progression of Alport's nephropathy to ESRD? Reduction in the quantity of $\alpha 3(\text{IV})$, $\alpha 4(\text{IV})$, and $\alpha 5(\text{IV})$ chains in GBM, as likely occurs in thin basement membrane nephropathy, probably has

consequences different from complete loss of these chains, as occurs in most males with XLAS and most patients with ARAS. There is increasing information about the molecular events that occur consequent to the loss of the $\alpha 3(\text{IV})$ – $\alpha 4(\text{IV})$ – $\alpha 5(\text{IV})$ network. In the GBM, the normal transition from the $\alpha 1(\text{IV})_2$ – $\alpha 2(\text{IV})_1$ network of nascent glomeruli to the $\alpha 3(\text{IV})$ – $\alpha 4(\text{IV})$ – $\alpha 5(\text{IV})$ network of mature glomeruli fails to occur, and $\alpha 1(\text{IV})$ and $\alpha 2(\text{IV})$ chains accumulate in Alport's glomeruli as the disease progresses.^{26,27} Alport's GBM shows overexpression of other matrix proteins that are normally absent from GBM or present in scant quantities, including type V collagen, type VI collagen, laminin $\alpha 2$ chain, and fibronectin. These alterations in GBM composition are unique to AS.^{26,28} Both glomerular endothelial cells and podocytes appear to contribute to the accumulation of these proteins in Alport's GBM. Alterations in glomerular extracellular matrix are accompanied by changes in glomerular cell behavior, including expression of transforming growth factor $\beta 1$, integrins, and matrix metalloproteinases.²⁹ Activation of fibrogenic pathways in the renal interstitium presumably represents a downstream consequence of glomerular disease.

Treatment

Clinical trials of therapy for Alport's nephropathy have not been conducted. The availability of canine and murine models of AS should allow the testing of genetic or pharmacologic therapies to select promising treatments for human trials.^{30,31} As in other chronic glomerulopathies, deterioration of glomerular filtration rate (GFR) in AS is closely correlated with tubulointerstitial fibrosis.³² It is possible that therapies that interfere with glomerular and interstitial fibrosis may be of benefit in AS patients, without correcting the primary abnormalities of type IV collagen expression. Cyclosporine appeared to stabilize renal function in a small, uncontrolled study of AS males³³; however, another study described rapid development of cyclosporine nephrotoxicity in treated patients.³⁴

Results of studies of angiotensin blockade in animals with AS suggest that this approach could be beneficial in human AS.³⁵ There have as yet been no clinical trials of renin-angiotensin system blockade in human AS, although a study suggesting delay in progression to ESRD in patients treated with angiotensin-converting enzyme (ACE) inhibition, compared with untreated historical controls, has appeared in abstract form.³⁶ Reversal of murine ARAS by bone marrow transplantation has been described,^{37,38} but data from a subsequent study suggested that the therapeutic effect was attributable to irradiation.³⁹

Transplantation

At present, renal transplantation is the only available treatment of AS. Graft survival in patients with familial nephritis is equivalent to that in patients with other diagnoses. However, anti-GBM glomerulonephritis involving the renal allograft is a rare but dramatic manifestation of AS, occurring in 2% to 3% of male AS patients who undergo transplantation. This is discussed further in Chapter 23.

Are women who are heterozygous for *COL4A5* mutations suitable kidney donors? Clearly, those with proteinuria, hypertension, or reduced GFR should not donate, and the same applies if there is any hearing loss. What about heterozygotes with hematuria but normal renal function and hearing? There is no long-term follow-up information on the impact of uninephrectomy in such women. But given the recent finding that 30% to

40% of heterozygous women may eventually develop ESRD, the risk that a heterozygous donor will ultimately develop significant renal impairment must be higher than for the usual kidney donor.

However, a common clinical scenario is a mother wishing to donate to her son with AS, and the wishes of the whole family should be thoughtfully considered.

THIN BASEMENT MEMBRANE NEPHROPATHY: FAMILIAL AND SPORADIC

Definition

Isolated glomerular hematuria may occur as a familial or sporadic condition and is often associated with a renal biopsy finding of excessively thin GBM. The term *benign familial hematuria* was used in the past to describe disease kindreds in which multiple individuals in several generations have isolated hematuria without progression to ESRD. More recently, thin basement membrane nephropathy (TBMN) has been used to identify both familial and sporadic isolated hematuria associated with attenuated GBM. It is likely that several disorders that differ at the molecular level are associated with GBM thinning, and in some instances, it is probably a normal variant. In general, the discussion that follows applies to both familial and sporadic TBMN.

Similar to AS, familial TBMN is an inherited GBM disorder manifested by chronic hematuria, but it differs clinically from AS in several important respects: (1) extrarenal abnormalities are rare; (2) proteinuria, hypertension, and progression to ESRD are unusual; (3) gender differences in expression of TBMN are not apparent; and (4) transmission is autosomal dominant. TBMN and early AS may be difficult to differentiate histologically because diffuse GBM attenuation is characteristic of both. However, the GBM of patients with TBMN remains attenuated over time, rather than undergoing the progressive thickening and multilamellation that occurs in AS.

Etiology and Pathogenesis

TBMN is an autosomal dominant condition, but a negative family history may not be reliable because patients are frequently unaware that they have relatives with hematuria. Familial TBMN has been localized to *COL4A3* or *COL4A4* in numerous kindreds^{40,41}; 50% or more of heterozygous carriers of a *COL4A3* or *COL4A4* mutation have hematuria.^{15,16} However, linkage to *COL4A3* and *COL4A4* has been excluded in other families with isolated hematuria, indicating that TBMN is a genetically heterogeneous condition.

Immunohistologic studies of type IV collagen in GBM of patients with TBMN have found no abnormalities in the distribution of any of the six α chains. Immunohistologic evaluation of GBM type IV collagen may therefore be useful in the differentiation of TBMN from AS (see later discussion).

Clinical Manifestations

It has been estimated that 20% to 25% of patients referred to a nephrologist for evaluation of persistent hematuria will prove to have thin GBM on renal biopsy. Individuals with TBMN typically have persistent microscopic hematuria that is first detected in childhood. In some patients, microscopic hematuria is intermittent and may not be detected until adulthood. Episodic macroscopic hematuria, often in association with upper respiratory

Figure 46.10 Thin basement membrane nephropathy. Electron micrographs of renal biopsy specimens. **A**, Normal glomerular capillary wall. **B**, Thin basement membrane nephropathy at the same magnification. Note the diffuse and uniform attenuation of the GBM and the lamina densa. (From Warrell DA, Cox TM, Firth JD, Benz EJ Jr [eds]: *Oxford Textbook of Medicine*. Oxford, Oxford University Press, 2003, p 322.)

infections, is not unusual. The hematuria of TBMN appears to be lifelong.

Overt proteinuria and hypertension are unusual in TBMN but have been reported. Some of these patients may have actually had AS, in which the predominant abnormality of GBM was attenuation rather than thickening and multilamellation. Other glomerular disorders, such as IgA nephropathy and focal or global glomerulosclerosis, may occur concurrently with TBMN.

Pathology

Light and immunofluorescence microscopy are unremarkable in typical cases of TBMN. Most patients exhibit diffuse thinning of the whole GBM and of the lamina densa (Fig. 46.10). GBM width is age and gender dependent in normal individuals. Both the lamina densa and the GBM increase rapidly in thickness between birth and 2 years of age, followed by gradual thickening into adulthood. GBM thickness in adult men (373 ± 42 nm) exceeds that in adult women (326 ± 45 nm).³¹ Each electron microscopy laboratory should establish a consistent technique for measuring GBM thickness and determine its own reference range for GBM width to make comparisons with published data meaningful. Typically, a value of 250 nm will accurately separate adults with normal GBM from those with TBMN.⁴² For children, the cutoff is in the range of 200 to 250 nm. Intraglomerular variability in GBM width is small in individuals with TBMN.

Diagnosis and Differential Diagnosis

If the family history indicates autosomal dominant transmission of hematuria, if there is no history of chronic renal failure, and if kidney and urinary tract imaging studies are normal, a presumptive diagnosis of TBMN can often be made without kidney biopsy (see Fig. 46.8). When family history is negative or unknown or there are atypical coexisting features, such as proteinuria and deafness, renal biopsy may be very informative. A finding of thin GBM may be further characterized by examining the distribution of type IV collagen α chains in the kidney. Normal distribution of these chains provides supportive although not conclusive evidence for a diagnosis of TBMN. Marked

variability in GBM width within a glomerulus in a patient with persistent microhematuria should raise suspicion of AS, although focal lamina densa splitting has been described in TBMN. Genetic analysis may confirm a heterozygous mutation in *COL4A3* or *COL4A4*.

Treatment

Patients with TBMN should be reassured but not lost to follow-up examination. The risk for chronic renal impairment is small but real. Urinalysis and measurement of blood pressure and renal function are recommended every 1 to 2 years.

FABRY'S DISEASE (ANDERSON-FABRY DISEASE)

Definition

Fabry's disease comprises the clinical and pathologic manifestations of hereditary deficiency of the enzyme α -galactosidase A (α -Gal A), resulting in the intracellular accumulation of neutral glycosphingolipids with terminal α -linked galactosyl moieties (globotriaosylceramide; Fig. 46.11). Anderson⁴³ and Fabry⁴⁴ each described the characteristic skin lesions of this condition in 1898 and noted the association of proteinuria with the skin lesion, for which Fabry coined the term *angiokeratoma corporis diffusum*.

Etiology and Pathogenesis

More than 100 mutations causing Fabry's disease have been identified in the gene for α -Gal A, which is located on the X chromosome. Most of the described mutations are associated with the classic Fabry phenotype, in which there is multisystem involvement. Certain missense mutations have been identified in patients with a mild phenotype limited to cardiac abnormalities.⁴⁵

Deficiency of α -Gal A leads to progressive intracellular accumulation of neutral glycosphingolipids, particularly those with α -galactosyl moieties, the most abundant of which is globotriaosylceramide (Gb3). Glycosphingolipids are normal constituents of the plasma membrane, the membranes of intracellular organelles, and circulate in association with apolipoproteins. The glycosphingolipids that accumulate in Fabry's disease are identical to those found in normal tissue. All tissues except red blood cells accumulate Gb3, with the highest concentrations found in the diseased kidney.

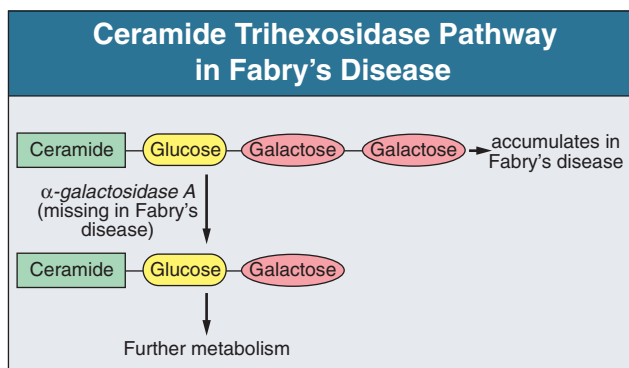

Figure 46.11 The ceramide trihexosidase pathway in Fabry's disease. α -Galactosidase A deficiency leads to tissue accumulation of trihexosylceramide.

Clinical Manifestations and Pathology

Classic Fabry's disease is a multisystem disorder, with prominent and potentially devastating involvement of the kidneys, heart, and peripheral and central nervous system. As expected for an X-linked disorder, severe clinical manifestations occur in hemizygous males, whereas heterozygous females exhibit a variable but typically less severe course. In affected males, the initial features of the disease are seen in childhood and early adolescence and consist of paresthesias and pain in the hands and feet with episodic pain crises. The course of the disease is variable but usually leads to ESRD in the third to sixth decade. Myocardial or cerebral infarctions are typical terminal events. Severe Fabry's disease in a female reflects extensive inactivation of the X chromosome carrying the normal α -Gal A allele.

Renal Defects

Although the earliest manifestation of renal involvement is a concentrating defect, the nephropathy of Fabry's disease typically is manifested as mild to moderate proteinuria, sometimes with microscopic hematuria, beginning in the third decade of life. Nephrotic syndrome is unusual. Urinary oval fat bodies, with a Maltese cross configuration when viewed with a polarizing microscope, are a result of the large amounts of glycosphingolipid in the urine (see Chapter 4, Fig. 4.4B). Deterioration of renal function is gradual, with hypertension and ESRD developing by the fourth or fifth decade of life. Heterozygous women typically display mild renal involvement but may develop ESRD.

Light microscopy shows striking glomerular changes (Fig. 46.12) with additional abnormalities of tubular epithelium and vessels. Glomerular visceral epithelial cells are enlarged and packed with small, clear vacuoles, which represent glycosphingolipid material that has been extracted during processing. Vacuoles may also be seen in parietal epithelial cells and the epithelial cells of the distal convoluted tubule and loop of Henle but only rarely in mesangial cells, glomerular endothelial cells, or proximal tubular epithelial cells. There is progressive segmental and global glomerulosclerosis. Vacuoles are also observed in endothelial cells and smooth muscle cells of arterioles and arteries.

On electron microscopy, there are abundant inclusions within lysosomes, particularly within visceral epithelial cells (Fig. 46.13). The inclusions (myelin figures) are typically round, comprising concentric layers of dense material separated by clear spaces. The layers may be arranged in parallel (zebra bodies).

Detachment of visceral epithelial cells from the underlying basement membrane may be observed. Inclusions are also observed in heterozygous females, although usually in smaller numbers than in affected males. Typical inclusions may be noted in excreted renal tubular cells.

The progression of Fabry's nephropathy to ESRD probably reflects two parallel processes. Visceral epithelial cell dysfunction, which results in proteinuria, is followed by visceral epithelial cell detachment and necrosis leading to capillary loop collapse and segmental sclerosis. Simultaneously, progressive impairment of arteriolar flow may develop, as enlarging endothelial cells impinge on vascular lumina, resulting in ischemic glomerular damage.

Heart Defects

Glycosphingolipid accumulation in coronary arterial endothelial cells and in the myocardium results in coronary artery narrowing, which may lead to angina, myocardial infarction, or congestive heart failure. Arrhythmias and valvular lesions have been

Figure 46.12 Light microscopy of a renal biopsy specimen in Fabry's disease. Glomerular epithelial cell glycosphingolipid deposition demonstrated by (A) vacuolation on hematoxylin and eosin staining (magnification $\times 20$) and (B) oil red O staining (magnification $\times 20$). (Courtesy Dr. Paolo Menè and Dr. Antonella Stoppacciaro, University of Rome.)

identified. Certain missense mutations affecting α -Gal A may present as isolated left ventricular hypertrophy.⁴⁵

Nervous System

Autonomic dysfunction is a prominent feature of Fabry's disease, commonly manifested by hypohidrosis, acral paresthesias, and altered intestinal motility. Cerebrovascular symptoms tend to appear during the fourth decade of life and include hemiparesis, vertigo, diplopia, dysarthria, nystagmus, nausea and vomiting, headache, ataxia, and memory loss. The vertebrobasilar circulation is preferentially involved. Symptoms are often recurrent. Life-threatening intracerebral hemorrhage and infarction are not unusual. Dementia arising from glycosphingolipid accumulation in small cerebral blood vessels has also been described.

Skin

Angiokeratomas usually appear during the second decade of life, presenting as dark red macules or papules of variable size (Fig. 46.14). Typical locations include the lower trunk, buttocks, hips, genitalia, and upper thighs. The number of lesions varies from none up to 40. On histologic examination, angiokeratomas consist of dilated small veins in the upper dermis, covered by hyperkeratotic epidermis. Telangiectasias may be noted, especially behind the ears.

Eyes

Characteristic corneal opacities are common in both men and women with Fabry's disease. These lesions, termed verticillata,

Figure 46.13 Electron micrograph of a renal biopsy specimen in Fabry's disease. Glycosphingolipid is deposited in cytoplasmic vacuoles in glomerular visceral epithelial cells. Inset: Cytoplasmic vacuoles contain electron-dense material in parallel arrays (zebra bodies) and in concentric whorls (myelin figures). (Courtesy Dr. J. Carlos Manivel.)

Figure 46.14 Angiokeratoma in Fabry's disease. Note the multiple periumbilical angiokeratomas. (Courtesy Dr. S. Waldek.)

are identified by slit-lamp examination and are whorls of whitish discoloration that radiate from the center of the cornea. Cataracts and dilated conjunctival or retinal vessels may be observed.

Lungs

Dyspnea and cough are common in men with Fabry's disease, often with airflow limitation on spirometry. This may be a consequence of fixed narrowing of the airways due to glycosphingolipid accumulation.

Diagnosis

Diagnosis of affected males can usually be made on clinical grounds with the additional information from slit-lamp examination of the eye. The diagnosis should be confirmed by demonstrating decreased or absent α -Gal A activity in serum, leukocytes, cultured skin fibroblasts, or tissue. Atypical variants may have enzyme activity up to 35% of normal. Heterozygous females have intermediate levels of α -Gal A activity, but values may be in the low-normal range, making measurement of enzyme activity an insensitive way of diagnosing carriers. Alternatives include

careful slit-lamp eye examination, measurement of urinary ceramide digalactoside and trihexoside, and molecular techniques using restriction fragment length polymorphisms of either the α -Gal A gene or closely linked markers on the X chromosome. Identification of carriers is particularly relevant when family members are being considered as living kidney donors.

Fabry's disease should be considered in patients with unexplained ESRD,⁴⁶ especially if left ventricular hypertrophy is present or there is a history of stroke.⁴⁷

Treatment

Until recently, clinicians could offer little beyond palliative, symptomatic care, but the introduction of enzyme replacement therapy with recombinant human α -Gal A (agalsidase) has transformed the treatment of Fabry's disease. Randomized clinical trials showed that agalsidase administration during 5 to 6 months resulted in reduced plasma and urine Gb3; amelioration of neuropathic pain; enhanced quality of life; clearing of Gb3 deposits from kidney, heart, and skin; and improved cerebral blood flow.^{48,49} A multicenter longitudinal study showed that agalsidase stabilized renal function in patients with mild to moderate renal impairment at baseline and reduced left ventricular mass in those with left ventricular hypertrophy at baseline during 1 to 2 years of treatment.⁵⁰ In patients with ESRD, agalsidase infusion may be combined with hemodialysis because there is little clearance of the enzyme by dialysis.⁵¹ Agalsidase therapy has been recommended for all affected males and symptomatic carrier females.⁵²

Renal transplantation is an effective treatment of advanced Fabry's nephropathy but does not ameliorate the extrarenal manifestations. Transplanted kidneys from deceased donors or unaffected living donors may develop glycosphingolipid inclusions, but these are generally infrequent and clinically insignificant. Fabry heterozygotes should not become kidney donors. Coronary artery and cerebrovascular disease are the major causes of death in patients with Fabry's disease who have undergone renal transplantation. Renal allograft recipients with Fabry's disease are candidates for agalsidase treatment.⁵²

Fabry's Disease in Childhood

Because it is often not appreciated that the signs and symptoms of Fabry's disease, particularly pain crises, acroparesthesias, angiokeratomas, and corneal opacities, typically have their onset in childhood, the diagnosis is frequently delayed until well into adult life.⁵³ Symptomatic children with Fabry's disease are potential candidates for agalsidase therapy, and treatment trials in children are now under way.

NAIL-PATELLA SYNDROME

Definition

Nail-patella syndrome (NPS) is an autosomal dominant condition characterized by hypoplasia or absence of the patellae, dystrophic nails, dysplasia of the elbows and iliac horns, and renal disease.

Etiology and Pathogenesis

The NPS locus was identified in 1998 as the LIM homeodomain transcription factor *LMX1B*.^{54,55} A variety of mutations in *LMX1B*

have been found in NPS patients, including missense, splicing, insertion or deletion, and nonsense alterations. The results of *in vitro* studies of the transcriptional effects of mixing wild-type and mutant *LMX1B* suggest that NPS results from haploinsufficiency of *LMX1B*, rather than a dominant-negative effect.⁵⁶ Although *LMX1B* appears to be important for normal limb and kidney development, the precise mechanisms for the renal effects of *LMX1B* mutations remain under investigation.

Clinical Manifestations

Renal Defects

Clinically apparent renal disease occurs in less than half of NPS patients. The nephropathy is usually benign, with about a 10% risk for progression to ESRD. The clinical signs of NPS nephropathy appear in adolescence or young adulthood and typically include microscopic hematuria and mild proteinuria, although some patients develop nephrotic syndrome and mild hypertension. The severity of the renal manifestations may differ substantially in related individuals.

Skeletal Defects

The patellae are absent or hypoplastic in more than 90% of patients with NPS (Fig. 46.15) and may be associated with effusions and osteoarthritis of the knees. In about 80% of patients, there are osseous processes projecting posteriorly from the iliac wings (iliac horns), which are pathognomonic (Fig. 46.16). Anomalies of the elbows include aplasia, hypoplasia, and posterior processes at the distal ends of the humeri.

Nails

Nail abnormalities occur in about 90% of patients and are typically bilateral and symmetric. Fingernails are more commonly affected than toenails. The nails may be absent or dystrophic with discoloration, koilonychia, longitudinal ridges, or triangular lunulae.

Figure 46.15 Nail-patella syndrome. Clinical (A) and radiologic (B) appearance of absence of the patellae. (Courtesy Dr. R. Vernier.)

Figure 46.16 Nail-patella syndrome. Iliac horns (arrows). (Courtesy Dr. R. Vernier.)

Figure 46.17 Electron micrograph of renal biopsy specimen in nail-patella syndrome. The GBM appears moth-eaten on routine staining. CL, capillary lumen; US, urinary space. (Courtesy Dr. R. Vernier.)

Pathology

The only specific features of the NPS renal lesion are ultrastructural; electron microscopy shows multiple irregular lucencies of the GBM, giving it a moth-eaten appearance (Fig. 46.17). Such lucencies may also be observed in the mesangium. These lucent areas sometimes contain cross-banded collagen fibrils, which are more easily observed after staining with phosphotungstic acid (Fig. 46.18). The fibrils, which are type III collagen,⁵⁷ tend to be arranged in clusters, and the surrounding GBM is often thickened. They may be observed in the kidneys in the absence of clinically evident renal disease, but they have not been found in extraglomerular basement membranes. Cross-banded fibrils of type III collagen have been seen in GBM of patients with glomerular disease who lack nail or skeletal abnormalities, sometimes as a familial condition with autosomal recessive inheritance (collagen type III glomerulopathy; see Chapter 27). It is uncer-

tain whether there is a pathogenetic relationship between collagen type III glomerulopathy and NPS.

Treatment

There is no specific therapy for the nephropathy of NPS. There has been no reported recurrence in transplanted kidneys. Because NPS is an autosomal dominant disorder, careful evaluation of potential living related kidney donors for features of the disease is essential.

Inherited Disorders of Sodium and Water Handling

Peter Gross, Peter Heduschka

Glomerular filtration yields about 150 l of water, 21,000 mmol of Na^+ , and 750 mmol of K^+ in a healthy individual in 24 hours, yet only minute fractions of these quantities are excreted eventually as urine. This remarkable volume reduction is accomplished by highly active tubular transport. Inherited defects of tubular transport proteins may thus lead to major fluid and electrolyte derangements. This chapter describes disorders arising in the thick ascending limb of Henle's loop and thereafter; proximal tubular disorders are described in Chapter 48 and disturbances of acidification in Chapter 12.

Genetic studies have unraveled the molecular basis of most of the inherited tubular disorders, establishing specific diagnoses more clearly and explaining the corresponding pathogenesis more reliably than was possible before. It is hoped that improved therapies will be developed in time. Diagnostic genetic testing is available for a number of the disorders discussed in this chapter (see www.genetests.org).

PHYSIOLOGY OF SODIUM AND WATER REABSORPTION

Sodium Reabsorption

In all tubular epithelial cells, a basolateral energy requiring Na^+, K^+ -ATPase will ensure that intracellular Na^+ is kept at low levels while K^+ is high. The resulting concentration gradients of Na^+ across the apical cell membrane drive passive Na^+ reabsorption from the tubular lumen to the cell interior. Apical Na^+ channels and transport proteins serve to regulate the Na^+ reabsorption, and the proteins involved differ from one tubular segment to the next.

In the proximal tubule, an apical Na^+/H^+ exchange protein (NHE3) facilitates most of the Na^+ reabsorbed. It is inhibitable by acetazolamide. The thick ascending limb has an apical $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ cotransporter (NKCC2; Fig. 47.1) that can be blocked by furosemide and bumetanide. For efficient Na^+ reabsorption by NKCC2, it is required that K^+ be returned through a K^+ channel called ROMK from the cell to the low K^+ tubular fluid (see Fig. 47.1). It is also important that sodium transport by this segment is dependent on a basolateral Cl^- channel (ClC-Kb) and an accessory protein of ClC-Kb called barttin (see Fig. 47.1).

The distal convoluted tubule reabsorbs Na^+ by a unique apical Na^+/Cl^- cotransporter (NCCT). The protein is specifically inhibited by thiazides (Fig. 47.2). A basolateral ClC-Kb chloride channel is also necessary for efficient sodium reabsorption.

In the collecting duct, an apical Na^+ channel called ENaC regulates Na^+ reabsorption. Amiloride and triamterene specifically block ENaC, whereas the mineralocorticoid aldosterone

upregulates ENaC (Fig. 47.3). An overview of tubular proteins of Na^+ reabsorption and their corresponding inheritable disorders is provided in Figure 47.4.

Water Reabsorption

In most nephron segments, water follows NaCl passively through aquaporins, constitutively open water transport proteins in apical and basolateral tubular cell membranes. However, the collecting duct is different. It is equipped with apical aquaporin 2, which is the sole water channel in the kidney that can be regulated on a short-term basis by vasopressin. In this way, the collecting duct provides for eventual fine-tuning of water reabsorption or excretion (Fig. 47.5).

DISORDERS OF SODIUM HANDLING

An overview of inherited disorders of Na^+ transport is shown in Figure 47.6. On clinical grounds, it is possible to broadly distinguish four different phenotypes:

1. Hypokalemia and normal blood pressure (Bartter syndrome, Gitelman's syndrome).
2. Hypokalemia and high blood pressure (Liddle syndrome, apparent mineralocorticoid excess, glucocorticoid-remediable hyperaldosteronism, adrenal 17α -hydroxylase deficiency, adrenal 11β -hydroxylase deficiency).
3. Hyperkalemia and normal blood pressure (pseudohypoaldosteronism, adrenal 21 -hydroxylase deficiency, adrenal aldosterone synthase deficiency).
4. Hyperkalemia and high blood pressure (Gordon's syndrome).

Some of the disorders are caused by mutated renal transport proteins (e.g., Gitelman's syndrome). In others, the genetic defect resides in the adrenals, and the changes of adrenal mineralocorticoids and glucocorticoids bring about the renal phenotype.

CONDITIONS WITH HYPOKALEMIA, METABOLIC ALKALOSIS, AND NORMAL BLOOD PRESSURE

Bartter Syndrome

Bartter syndrome is rare and is manifested in childhood or in the perinatal period with severe hypokalemia, metabolic alkalosis, and low-normal blood pressure, all of which are caused by tubular wasting of Na^+ and Cl^- .¹ In contrast, Gitelman's syndrome is mostly a disorder of adults, and hypomagnesemia is a defining feature.²

Figure 47.1 Electrolyte transport in the thick ascending limb of the loop of Henle. The furosemide-sensitive $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ (NKCC2) cotransporter is driven by low intracellular Na^+ and Cl^- concentrations produced by the $\text{Na}^+\text{-K}^+\text{-ATPase}$ pump, the $\text{K}^+\text{-Cl}^-$ cotransporter, and the basolateral Cl^- channel (CIC-Kb). The β subunit (barttin) is crucial for normal functioning of the CIC-Kb channels. Apical K^+ recycling through the low-conductance, ATP-sensitive renal medullary K^+ (ROMK) channel ensures the efficient functioning of the NKCC2 cotransporter.

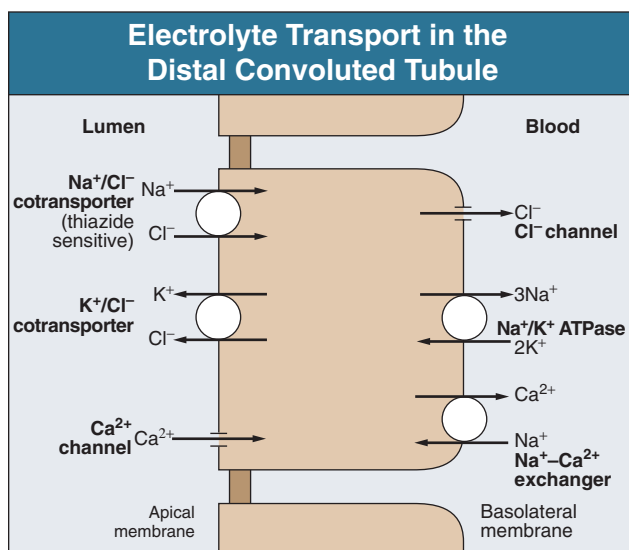

Figure 47.2 Electrolyte transport in the distal convoluted tubule. Reabsorption of Na^+ and Cl^- occurs across the apical membrane by the thiazide-sensitive $\text{Na}^+\text{-Cl}^-$ cotransporter (NCCT), and these ions leave the cell through the Cl^- channels and through the $\text{Na}^+\text{-K}^+\text{-ATPase}$ pump. Calcium ions enter the cell through the Ca^{2+} channels and exit through the $\text{Na}^+\text{-Ca}^{2+}$ exchanger.

Pathogenesis

Bartter syndrome is due to dysfunction of the thick ascending limb and is caused by inactivating mutations of each of its major transport proteins (NKCC2, Bartter syndrome type 1; ROMK, type 2; CIC-Kb, type 3; barttin, type 4) (Fig. 47.7; see also Fig. 47.1).³⁻⁶ The pathogenic consequences of these mutations are broadly similar in all four varieties except that the more severe phenotypes (types 1, 2, and 4) are manifested earlier in life.

Loss of function of any one of the four transport proteins will impair NaCl reabsorption by the thick ascending limb, increas-

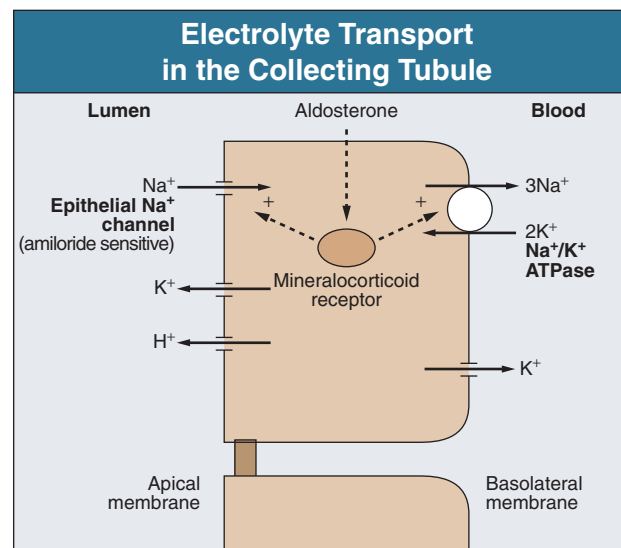

Figure 47.3 Electrolyte transport in the principal cell of the collecting tubule. Reabsorption of Na^+ occurs through the amiloride-sensitive epithelial Na^+ channel (ENaC). Its uptake is coupled to K^+ and H^+ secretion. Aldosterone increases the activity of ENaC and $\text{Na}^+\text{-K}^+\text{-ATPase}$, which increases Na^+ reabsorption and K^+ and H^+ secretion, resulting in hypokalemic alkalosis. Cortisol is also a ligand for the mineralocorticoid receptor but is normally removed by oxidation by 11β -hydroxysteroid dehydrogenase to cortisone.

ing the delivery of salt to the distal nephron. NaCl reabsorption is stimulated in those segments but compensates only partially for the salt wasting; it is associated with distal secretion of K^+ and H^+ . The net loss of NaCl from the nephron will cause plasma volume contraction, low-normal blood pressure, and secondary hyperaldosteronism. The loss of K^+ and H^+ will be followed by severe hypokalemia and metabolic alkalosis. Hypokalemia and increased angiotensin II also stimulate prostaglandin E_2 production.

Reduced Cl^- absorption in the loop of Henle inhibits voltage-driven paracellular absorption of Ca^{2+} , causing hypercalciuria, an important feature of Bartter syndrome that may be associated with nephrocalcinosis.

Inactivating mutations of barttin also cause deafness because barttin-dependent chloride transport is crucial to endolymph production in the inner ear.⁶ In some individuals with mutation of CIC-Kb (type 3), there is a mixed Bartter and Gitelman's syndrome.⁷ In these patients, the features of Bartter syndrome are associated with hypomagnesemia and hypocalciuria. Age at presentation is 1 month to 29 years. This mixed syndrome may be explained by the overlapping distribution of CIC-Kb, which is also expressed in the distal tubule, the site affected in Gitelman's syndrome.⁷ Finally, gain-of-function mutations in the extracellular calcium ion-sensing receptor also cause a Bartter-like syndrome.⁸ The receptor is normally expressed in the thick ascending limb, and its activation inhibits salt reabsorption similar to furosemide; in addition, this syndrome is associated with hypercalcemia.⁸

Clinical Manifestations

Bartter syndrome from mutations in NKCC2, ROMK, or barttin has a more severe phenotype than that caused by mutations of CIC-Kb. The more severe phenotype typically presents in the perinatal period and is called antenatal Bartter syndrome. The milder variety is called classic Bartter syndrome.

Figure 47.4 Pathways and mediators involved in Na^+ reabsorption. Almost 60% of the filtered Na^+ is reabsorbed in the proximal tubule. The distal portions of the nephron reabsorb the remainder. The chief mediators involved in Na^+ reabsorption and disorders resulting from their mutations are shown in boxes. PHA, pseudohypoaldosteronism.

The clinical features of antenatal Bartter syndrome include hypokalemia and metabolic alkalosis in a newborn with vomiting and failure to thrive. There may also be a history of polyhydramnios and premature delivery. Polyuria, hypercalciuria, and high urinary chloride concentrations are characteristic. Nephrocalcinosis may be manifested later in life. A prenatal diagnosis of Bartter syndrome may be made by demonstration of high Cl^- concentrations in amniotic fluid.

Patients with classic Bartter syndrome develop normally during the first 2 to 5 years of life. Thereafter, vomiting, polyuria, recurrent episodes of dehydration, and fever may become apparent. Carpopedal spasms and fatigue are common. Many children show developmental delay. The blood pressure is low normal. The laboratory features are comparable to those described previously, but nephrocalcinosis is usually absent.

Diagnosis

A newborn or a young child with vomiting, dehydration, low-normal blood pressure, severe hypokalemia, and metabolic alkalosis is likely to have Bartter syndrome if there is high urinary Cl^- and K^+ . The suspected diagnosis will receive further support if supplements of K^+ and Cl^- are inefficient in correcting the severe hypokalemia and the blood pressure. Diuretics will not be found in the urine. Hypomagnesemia and hypocalciuria are

Figure 47.5 Water reabsorption in the distal tubule. The aquaporin AQP2, which is exclusively present in the principal cells of the collecting tubules and ducts, is the chief vasopressin-regulated water channel. Activation of cAMP-dependent protein kinase A mediates protein phosphorylation that triggers exocytic insertion of AQP2 channels into the apical membrane. These channels increase the water permeability of the apical membrane, facilitating water transport.

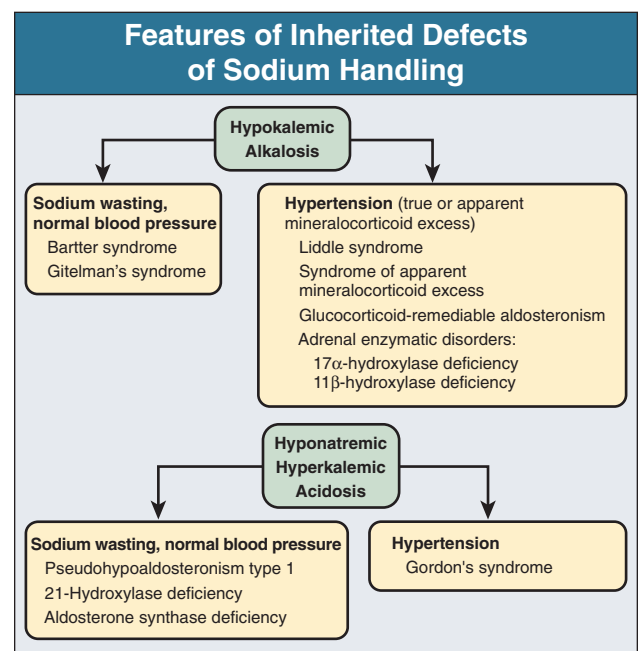

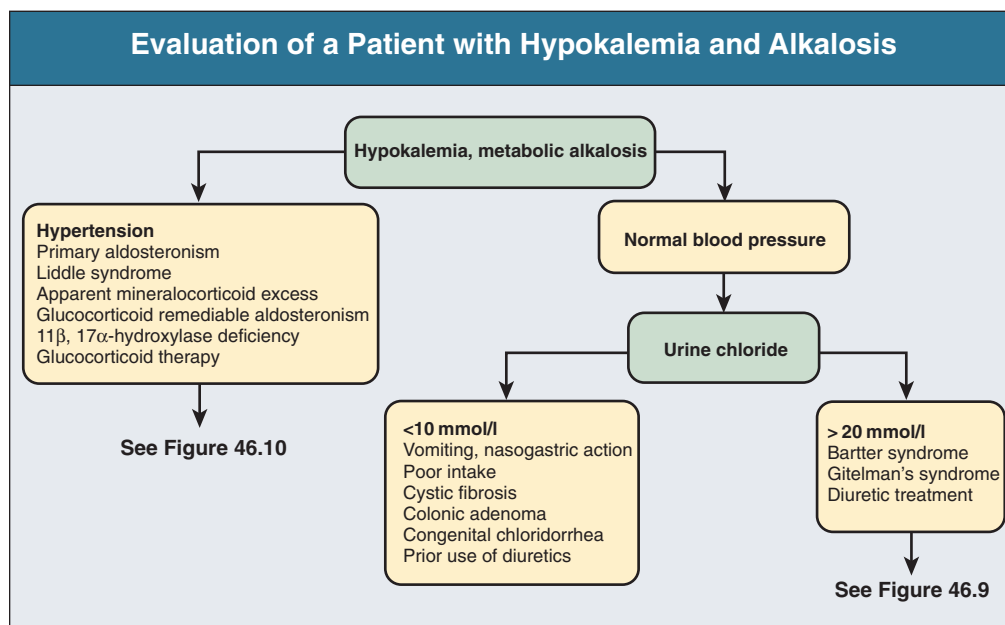

Figure 47.6 Features of inherited defects of sodium handling.

Inherited Single Gene Defects of Sodium and Water Handling			
Syndrome	Inheritance	Gene Localization	Gene Product
Neonatal Bartter syndrome	AR	15q	Na-K-2Cl cotransporter <i>NKCC2</i>
Neonatal Bartter syndrome	AR	11q	Renal potassium channel <i>ROMK</i>
Classic Bartter syndrome	AR	1p	Renal chloride channel <i>ClC-Kb</i>
Bartter syndrome with deafness	AR	1p	β -Subunit of <i>ClC-Kb</i> <i>Barttin</i>
Gitelman's syndrome	AR	16q	NaCl cotransporter <i>NCCT</i>
Liddle syndrome	AD	16p	Epithelial sodium channel <i>ENaC</i>
Syndrome of apparent mineralocorticoid excess	AR	16q	11 β -hydroxysteroid dehydrogenase type II
Glucocorticoid-remediable aldosteronism	AD	8q	Aldosterone synthase <i>CYP11B2</i>
Pseudohypoaldosteronism type I	AD	4p	Mineralocorticoid receptor

Figure 47.8 Evaluation of a patient with hypokalemia and metabolic alkalosis.

absent. Secondary hyperaldosteronism is a regular feature. In questionable cases, genotyping should be used to confirm the diagnosis.

Differential Diagnosis

In syndromes of chronic severe hypokalemia with metabolic alkalosis, the differential diagnosis may be facilitated greatly by taking into consideration the associated blood pressure and the urinary chloride concentration (Fig. 47.8).

If there is hypertension, this points to disorders related to hyperaldosteronism. If, however, the syndrome is associated with a normal or low-normal blood pressure, extrarenal or renal Cl^- and Na^+ losses are the culprits. Extrarenal loss of sodium occurs in diarrhea, vomiting, or burns. It is characterized by very low Cl^- concentrations in the urine, often as low as 1 mmol/l. By contrast, renal loss of salt with high urinary Cl^- and Na^+ is typical of Bartter syndrome, Gitelman's syndrome, and diuretic use. The absence of hypomagnesemia and hypocalciuria will then

Features Differentiating Bartter and Gitelman's Syndromes			
Features	Neonatal Bartter Syndrome	Classic Bartter Syndrome	Gitelman's Syndrome
Age at onset	Neonatal period	Infancy/childhood	Childhood/late
Maternal hydramnios	Common	Rare	Absent
Polyuria, polydipsia	Marked	Present	Rare
Dehydration	Present	Often present	Absent
Tetany	Absent	Rare	Present
Growth retardation	Present	Present	Absent
Urinary calcium	Very high	Normal or high	Low
Nephrocalcinosis	Present	Rare	Absent
Serum magnesium	Normal	Occasionally low	Low
Urine prostaglandins (PGE ₂)	Very high	High or normal	Normal
Response to indomethacin (improvement of hypokalemia and renal salt wasting)	Good	Good	Rare

Figure 47.9 Features differentiating Bartter and Gitelman's syndromes. In addition to these clinical and laboratory features, molecular diagnosis is now possible (see text). PGE₂, prostaglandin E₂.

argue against Gitelman's syndrome (Fig. 47.9). Genotyping is recommended to diagnose overlap of Bartter and Gitelman's syndromes.

Treatment

Patients with the neonatal form of Bartter syndrome have marked fluid and electrolyte disturbances that need to be corrected carefully. Saline infusion may be required in the neonatal period. Potassium chloride supplementation is always necessary.⁹ Addition of spironolactone or triamterene may be useful in correcting hypokalemia, but the effect of these drugs is usually transient. Angiotensin-converting enzyme (ACE) inhibitors have been used for correction of hypokalemia, with conflicting results. Magnesium deficiency may aggravate renal K⁺ wasting and, if present, should be corrected.

The efficacy of long-term treatment with prostaglandin synthase inhibitors, such as indomethacin (1 to 3 mg/kg per 24 hours) or ibuprofen, is well established.⁹ They act by reducing cortical perfusion and decreasing delivery of Na⁺ and Cl⁻ to the distal nephron, ameliorating many of the features of the disease. The amplifying effect of prostaglandins on the renal tubules is also neutralized. Treatment results in reduction of polyuria and polydipsia, restitution of normal growth and activity, and correction of hypokalemia; serum K⁺, however, rarely exceeds 3.5 mmol/L. Plasma levels of renin and aldosterone reduce to the normal range.

Outcome

If not treated, patients may succumb to episodes of dehydration, electrolyte disturbance, or intercurrent infection. With appropriate therapy, most children improve clinically and show catch-up growth; pubertal and mental developments are usually normal. Lifelong therapy is needed. Chronic tubulointerstitial nephropathy due to persistent hypokalemia, hypercalciuria, and nephrocalcinosis may lead to progressive decline in renal function. There are anecdotal reports of renal transplantation in patients with end-stage renal disease. The biochemical parameters return to normal after transplantation.

Gitelman's Syndrome

Gitelman's syndrome is an autosomal recessive condition also characterized by hypokalemic metabolic alkalosis but with hypocalciuria and hypomagnesemia.

Pathogenesis

The similarity between the features of Gitelman's syndrome and those caused by thiazide administration originally suggested that the defect might be in the distal convoluted tubule. The condition has now been linked to inactivating mutations in the gene for NCCT (see Figs. 47.2 and 47.4).¹⁰ Loss of NCCT function results in Na⁺ and Cl⁻ wasting from this segment, leading to hypovolemia with secondary activation of the renin-aldosterone system. The resulting increase in collecting tubule Na⁺ reabsorption is, however, counterbalanced by K⁺ and H⁺ excretion, causing hypokalemic alkalosis. The distal convoluted tubule normally reabsorbs only 7% to 8% of the filtered Na⁺ and Cl⁻ load. The degree of volume contraction, the stimulation of the renin-angiotensin system, and the amount of K⁺ loss are therefore not substantial enough to stimulate prostaglandin E₂ production.

The hypocalciuria is due to the associated plasma volume contraction. The renal magnesium wasting is caused by down-regulation of the epithelial Mg²⁺ channel TRPM6 in distal convoluted tubules.

Clinical Manifestations and Diagnosis

Most adults believed to have Bartter syndrome will be found to suffer from Gitelman's syndrome, and this diagnosis is not very rare. The severity of symptoms varies widely. More severely affected patients complain of generalized and muscle weakness, inability to work for extended periods, salt craving, and a preference for licorice. Cardiac disturbances, muscle cramps, and tetany are only exceptionally present. Chondrocalcinosis of the knees does occur later in life; it is a consequence of hypomagnesemia. Laboratory evaluation will show moderate hypomagnesemia, severe hypokalemia, hypocalciuria, high urinary chloride concentration, and absence of thiazides from the urine. The

Features of Liddle Syndrome, Apparent Mineralocorticoid Excess, and Glucocorticoid-Remediable Aldosteronism			
Features	Liddle Syndrome	AME	GRA
Inheritance	Autosomal dominant	Autosomal recessive	Autosomal dominant
Chief features	Significant hypertension, polyuria, growth retardation	Low birth weight, early-onset hypertension, polyuria, growth retardation	Significant hypertension, hemorrhagic stroke
Plasma aldosterone	Reduced	Reduced	Elevated
Plasma renin activity	Reduced	Reduced	Reduced
Urinary mineralocorticoid metabolites	Normal	Elevated ratios of THF + alloTHF to THE; free cortisol to cortisone	Elevated cortisol C-18 oxidation products
Response of the hypertension to			
Glucocorticoids	No	Satisfactory	Satisfactory
Triamterene	Satisfactory	Satisfactory	Satisfactory
Spironolactone	No	Satisfactory	Satisfactory

Figure 47.10 Features of Liddle syndrome, apparent mineralocorticoid excess (AME), and glucocorticoid-remediable aldosteronism (GRA). These syndromes are all characterized by hypokalemia, metabolic alkalosis, and hypertension. THE, tetrahydrocortisone; THF, tetrahydrocortisol.

blood pressure will be in the low-normal range. These findings establish the diagnosis. Genotyping should be performed in questionable or incomplete syndromes.

Treatment

There is no consensus on the best mode of treatment. Magnesium aspartate (5 to 15 mmol Mg²⁺/day), magnesium oxide, and potassium supplements are usually given to improve muscle weakness or cramps. However, dosing may be limited by diarrhea and abdominal discomfort. In exceptional cases, parenteral Mg²⁺ has been infused. Indomethacin, cyclooxygenase 2 inhibitors, and spironolactone are usually not helpful. The long-term prognosis for cardiac and renal function as well as for general health is good.

CONDITIONS WITH HYPOKALEMIA, METABOLIC ALKALOSIS, AND HYPERTENSION

Conditions with hypokalemia, metabolic alkalosis, and hypertension all have true or apparent mineralocorticoid excess.

Liddle Syndrome (Pseudohyperaldosteronism)

Liddle syndrome is an autosomal dominant syndrome of hypertension and variable degrees of hypokalemic metabolic alkalosis. The patients resemble those with primary hyperaldosteronism, but levels of mineralocorticoid hormones are not increased. Renin and aldosterone are suppressed, and there is no response to spironolactone.¹¹ However, triamterene and amiloride, aldosterone-independent inhibitors of distal Na⁺ transport, correct hypertension, renal K⁺ loss, and hypokalemia.¹²

Pathogenesis

Liddle syndrome is related to mutations of the β or γ subunit of the collecting duct sodium channel ENaC.¹³ The mutations result in truncations of the cytoplasmic C-terminal tail of the affected subunits. Collecting duct sodium reabsorption is dependent on the channel density present in the apical cell membrane. Channel density is regulated by removal of ENaC from the cell membrane, ubiquitination, and degradation. In Liddle syndrome,

the mutated ENaC protein cannot be recognized by NEDD4, a ubiquitin ligase protein; hence, the channels remain in the cell membrane for prolonged periods.¹² This action results in enhanced sodium reabsorption, hypertension, and hypokalemic alkalosis (see Fig. 47.3).

Clinical Manifestations and Diagnosis

Liddle syndrome is a rare disorder of hypertension in teenage children¹² that is associated with hypokalemic metabolic alkalosis and low blood levels of renin and aldosterone. The original patient developed renal failure from an unknown cause and eventually underwent transplantation.¹⁴ Thereafter, her blood pressure normalized, and renin and aldosterone responded normally to provocative measures.

This condition should be differentiated from primary hyperaldosteronism, apparent mineralocorticoid excess, and glucocorticoid-remediable aldosteronism (Fig. 47.10) as well as 11 β -hydroxylase (steroid 11 β -monooxygenase) or 17 α -hydroxylase (steroid 17 α -monooxygenase) deficiency. Activating mutations of the mineralocorticoid receptor have been reported and should also be differentiated.¹⁵

Treatment

Therapy consists of sodium restriction and K⁺ supplements. Triamterene directly inhibits apical Na⁺ channels, resulting in increased urinary Na⁺ and decreased K⁺ excretion and resolution of hypertension. Amiloride also normalizes the blood pressure and K⁺ levels. However, most patients continue to have growth retardation. Because the pathogenetic disorder is not correctable with age, lifelong therapy is required.

Apparent Mineralocorticoid Excess

Pathogenesis

Apparent mineralocorticoid excess (AME) is an autosomal recessive condition resulting from deficiency of the type II (renal and placental) isoform of the enzyme 11 β -hydroxysteroid dehydrogenase. Clinical features of this condition closely mimic those of Liddle syndrome.¹⁶

In normal conditions, aldosterone is the chief mineralocorticoid regulating electrolyte and water balance, through its effects

on distal renal tubules and cortical collecting ducts. After binding to the mineralocorticoid receptor, aldosterone increases synthesis of various proteins, chiefly Na^+/K^+ -ATPase on the basolateral surface and ENaC on the apical surface. These proteins increase Na^+ reabsorption and K^+ secretion in the distal tubules (see Fig. 47.3). Cortisol is also a ligand for the mineralocorticoid receptor and shows potent sodium-retaining activity. Cortisol is, however, normally metabolized by 11β -hydroxysteroid dehydrogenase to cortisone, which lacks such an action.

Loss-of-function mutations in the gene encoding 11 β -hydroxysteroid dehydrogenase have been detected in patients with the inherited form of AME.^{17,18} As a consequence, in the kidney, intracellular metabolic clearance of cortisol is severely impaired. The accumulation of cortisol causes nonspecific stimulation of the mineralocorticoid receptor. This will be followed by increased sodium reabsorption together with K⁺ and H⁺ secretion.

The 11 β -hydroxysteroid dehydrogenase is also expressed in the placenta. Reduced placental 11 β -hydroxysteroid dehydrogenase activity might be related to the low birth weight that is characteristic of AME patients.

Carbenoxolone and glycyrrhizic acid (found in licorice compounds) are potent inhibitors of this enzyme. Consumption of these agents may be associated with features similar to AME.

Clinical Manifestations and Diagnosis

AME is characterized by an onset of hypertension in childhood, hypokalemia, metabolic alkalosis, very low plasma levels of renin and aldosterone, and increased metabolites of cortisol in the urine. There may be a history of low birth weight and subsequent failure to thrive.

The diagnosis of AME is made by finding, on gas chromatography or mass spectroscopy, elevated urinary levels of hydrogenated metabolites of cortisol (tetrahydrocortisol plus allotetrahydrocortisol) compared with cortisone (tetrahydrocortisone). The ratio of urinary free cortisol to cortisone is also increased.¹⁹ Heterozygotes may occasionally show hypertension, normal serum K⁺, suppressed plasma renin and aldosterone, and moderately elevated urinary cortisol to cortisone metabolite ratio. A variant of AME, called AME type 2, has similar clinical features but a milder urinary steroid profile.²⁰

Treatment

Treatment with oral dexamethasone (0.75 to 5 mg/day) suppresses cortisol secretion, resulting in reduced Na^+ reabsorption and amelioration of hypertension and hypokalemia. Urinary concentrations of metabolites of cortisol and cortisone are only moderately affected. As in Liddle syndrome, patients respond to treatment with K^+ supplements combined with triamterene or amiloride. Spironolactone is effective in AME although not in Liddle syndrome. Renal transplantation is followed by normalization of cortisol metabolism, biochemical abnormalities, and hypertension.²¹

Glucocorticoid-Remediable Aldosteronism

Glucocorticoid-remediable aldosteronism (GRA) appears to be the most common monogenic form of human hypertension. It is an autosomal dominant condition. Patients present with typical features of primary hyperaldosteronism: hypertension, suppressed plasma renin activity, and hypokalemia. Unlike primary hyperaldosteronism (due to aldosterone-producing adrenal adenoma), hypersecretion of aldosterone in GRA can be reversed

by the administration of corticosteroids. Affected individuals have early-onset hypertension. There is a high prevalence of hemorrhagic stroke, largely as a result of ruptured intracranial aneurysms. Hypokalemia is typically mild but becomes more pronounced if diuretics are given. Potassium levels may occasionally be normal.

Pathogenesis

Patients with GRA have adrenocorticotrophic hormone (ACTH)-sensitive aldosterone production occurring in the zona fasciculata of the adrenal gland, which is usually responsible only for cortisol synthesis. Normal subjects synthesize aldosterone in the zona glomerulosa. Two isoenzymes of 11 β -hydroxylase are involved in the biosynthesis of aldosterone and cortisol: steroid 11 β -hydroxylase (CYP11B1) and aldosterone synthase (CYP11B2), respectively (Fig. 47.11). The genes for these isoenzymes are located close to each other on the long arm of chromosome 8. Unequal meiotic crossovers may produce hybrid genes by fusion of the promoter end of *CYP11B1* with the coding sequence of *CYP11B2*, so that *CYP11B2* encoding aldosterone synthase is inappropriately regulated by ACTH, as is *CYP11B1*.¹⁶ Abnormal expression of this chimeric gene in the adrenal zona fasciculata has been shown by *in situ* hybridization.

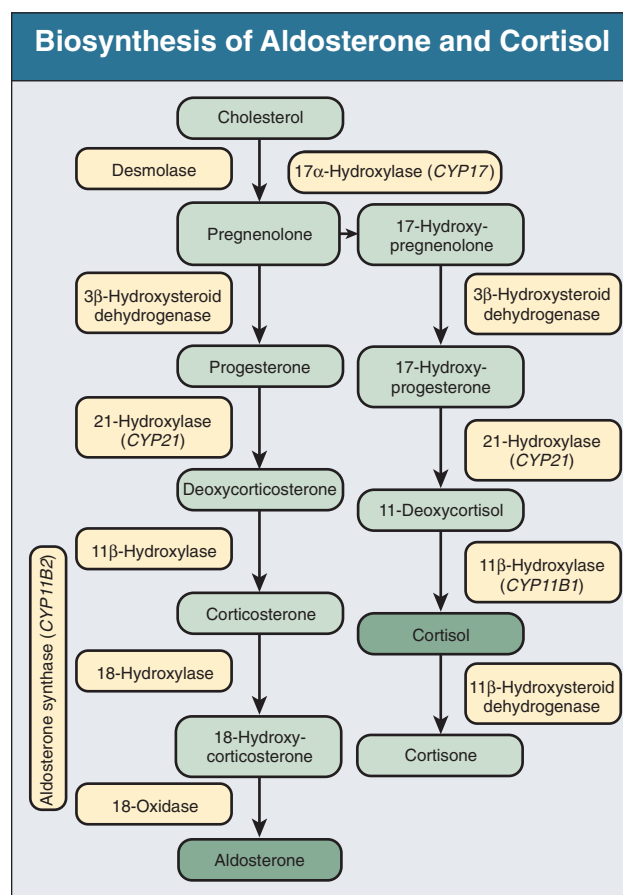

Figure 47.11 Biosynthesis of aldosterone and cortisol. Although cortisol and aldosterone both require 11 β -hydroxylation of precursors, these steps are catalyzed by different isoenzymes: steroid 11 β -hydroxylase (CYP11B1) and aldosterone synthase (CYP11B2), respectively. Aldosterone synthase also mediates two further conversions. Common enzyme deficiencies leading to derangement in sodium and water balance are shown in boxes. Cortisol is converted peripherally by 11 β -hydroxysteroid dehydrogenase to cortisone.

Diagnosis

Patients are often misdiagnosed as having primary hypertension. Hypertensive subjects with early-onset hypertension, early cerebral hemorrhage (<40 years), hypokalemia after treatment with diuretics, and refractoriness to standard antihypertensive medication are candidates for GRA testing. Similar to other genetic forms of hypertension (Liddle syndrome, AME, Gordon's syndrome), plasma renin activity is low. Although the mean aldosterone levels are high, determination of serum aldosterone has poor sensitivity as a screening test. In GRA, the aldosterone to renin ratio is elevated (>300), whereas in primary hypertension, AME, and Liddle syndrome, it is not.

The biochemical hallmark of GRA is overproduction and excretion of cortisol C-18 oxidation products, reflecting the action of aldosterone synthase on cortisol in the zona fasciculata. Large amounts of the so-called hybrid steroids (18-hydroxycortisol and 18-oxocortisol) can be found in the urine by specialized steroid laboratories.

Dexamethasone leads to suppression of blood aldosterone levels. When 0.5 mg of dexamethasone is given every 6 hours for 2 days, it suppresses aldosterone to undetectable levels (<4 ng/dl).

Direct screening for the hybrid gene *CYP11B1/CYP11B2* can also be performed and confirms the diagnosis (test can be obtained by www.brighamandwomens.org/gra/introduction.aspx).²²

Treatment

Treatment with low-dose corticosteroid is effective. Typically, 0.125 to 0.25 mg of dexamethasone or 2.5 to 5 mg of prednisolone is administered at bedtime. Therapeutic goals are normotension and normalization of biochemical markers (urinary 18-oxosteroid, serum aldosterone). Mineralocorticoid receptor antagonists (spironolactone, eplerenone) and ENaC antagonists such as amiloride and triamterene are also useful treatments. Antihypertensive therapy with β -blockers and ACE inhibitors is less likely to be effective.

Incomplete Phenotypes

Occasional patients with Liddle syndrome, AME, or GRA either do not express the complete phenotype or have mild clinical or biochemical features and are considered to have primary hypertension. Poor blood pressure control with conventional therapy should raise suspicion of an alternative diagnosis. Hypokalemia may not be a feature at presentation but develops with diuretic treatment. These conditions should be considered in patients with early-onset hypertension, failure to thrive, or a strong family history. The response to specific treatment with potassium-sparing diuretics or corticosteroids may suggest the diagnosis.

Adrenal Enzymatic Disorders

Inherited deficiency of 11 β - or 17 α -hydroxylase also causes mineralocorticoid excess with hypertension and hypokalemic metabolic alkalosis (see Fig. 47.11).

Deficiency of 17 α -hydroxylase (*CYP17*) impairs normal production of cortisol and adrenal androgens, resulting in pseudohermaphroditism in genetic males and primary amenorrhea in females. Cortisol deficiency results in increased ACTH secretion, low levels of renin and aldosterone, hypokalemia, metabolic alkalosis, and hypertension. Diagnosis is confirmed by finding excessive levels of deoxycorticosterone and corticosterone in the

urine. Administration of corticosteroids corrects the mineralocorticoid excess state.

Deficiency of 11 β -hydroxylase (*CYP11B1*) also impairs cortisol production but results in excessive androgens. Genetic females show pseudohermaphroditism, whereas males have virilization. The cortisol deficiency results in high blood levels of ACTH, deoxycortisol, and deoxycorticosterone; corticosterone levels are normal. Hypokalemia is variable. Diagnosis is confirmed by measurement of high levels of tetrahydro-11-deoxycortisol in the urine. Hypokalemia is variable. Treatment with corticosteroids corrects hypertension and hypokalemia; renin levels increase, but aldosterone remains low because of the biosynthetic defect.

CONDITIONS WITH HYPONATREMIA, HYPERKALEMIA, METABOLIC ACIDOSIS, AND NORMAL BLOOD PRESSURE

Conditions with hyponatremia, hyperkalemia, metabolic acidosis, and normal blood pressure have features of mineralocorticoid deficiency either because of a synthetic defect or because of end-organ resistance.

Pseudohypoaldosteronism

Pseudohypoaldosteronism (PHA) is a state of renal tubular (and other tissue) unresponsiveness to the action of aldosterone.²³ Symptoms start in early infancy with marked salt wasting and failure to thrive. PHA type 1 includes at least two major entities, with either renal or multiple target organ defects; the former is more common.

The inheritance of renal PHA type 1 is autosomal dominant but may be sporadic. Loss-of-function mutations of the gene for the mineralocorticoid receptor (located on 4p) have been identified.²⁴

Multiple end-organ PHA type 1 is a severe autosomal recessive disorder with multiple target organ resistance to the action of mineralocorticoids and is associated with inactivating mutations of α , β , or γ subunits of ENaC.²⁵ Differences between the two major types are shown in Figure 47.12.

Aldosterone Biosynthetic Defects

Patients with defects in aldosterone biosynthesis show salt wasting with hyponatremia, hyperkalemia, hypovolemia, and elevated plasma renin activity.²⁶

The enzymes cholesterol desmolase, 3 β -hydroxysteroid dehydrogenase, and 21-hydroxylase are required for synthesis of cholesterol and aldosterone, whereas aldosterone synthase is selectively responsible for aldosterone production in the adrenal cortex (see Fig. 47.11). Characteristics of diseases with aldosterone biosynthetic defects are shown in Figure 47.13.

Deficiency of 21-Hydroxylase

Mutations in the gene encoding 21-hydroxylase (*CYP21*) result in two major forms of the disease: a virilizing form and the more common salt-wasting type.²⁷ Patients with signs only of androgen excess are said to have the virilizing form. Female infants show varying degrees of pseudohermaphroditism, whereas affected males have normal or precocious sexual development. The salt-wasting type presents with hyponatremia, hyperkalemia, and moderate to severe volume depletion.

The diagnosis of 21-hydroxylase deficiency should be suspected in any newborn with genital ambiguity, salt wasting, or hypotension. Blood levels of progesterone, 17-hydroxyprogesterone, and dehydroepiandrosterone are raised several-fold above normal.

Features of Renal-Limited and Multisystem Forms of Pseudohypoaldosteronism Type I		
Feature	Renal-limited Form	Multisystem Form
Underlying defect	Mineralocorticoid receptor	Epithelial sodium channel
Affected organs	Kidney only	Kidney, sweat, salivary glands, distal colon
Inheritance	Autosomal dominant	Autosomal recessive
Salt wasting	Variable	Severe
Blood renin, aldosterone	Very high	Very high aldosterone
Sweat, salivary Na ⁺	Normal	High
Clinical features	Salt wasting variable, during stress	Severe salt wasting, often life-threatening (e.g., hyperkalemia, infections of the skin), often respiratory tract (mimics cystic fibrosis) destabilization
Treatment	Sodium chloride supplements for 1–3 years Carbenoxolone is effective in some patients (creates situation akin to AME)	Lifelong sodium chloride supplements, strict potassium restriction, prophylactic antibiotics to prevent skin sepsis, no response to carbenoxolone
Prognosis	Improvement usually by 6–8 years, need for salt supplement diminishes	Improvement rare with age

Figure 47.12 Features of renal-limited and multisystem forms of pseudohypoaldosteronism type 1. AME, apparent mineralocorticoid excess.

Patients with electrolyte imbalance and shock require resuscitation with intravenous fluids and salt supplements. Replacement therapy with oral hydrocortisone and 9 α -fludrocortisone is required long term. Some amelioration of the tendency to salt wasting may be seen with age because of the ability of children to regulate their dietary salt intake and maturation of proximal tubular function.

Reconstructive genital surgery may be required in females with genital ambiguity. Fetal DNA analysis and demonstration of elevated 17-hydroxyprogesterone in amniotic fluid allow prenatal detection of affected female infants. Treatment of the mother with dexamethasone from early in gestation reduces virilization of genitalia of the affected female fetus.

CONDITIONS WITH HYPERKALEMIA, METABOLIC ACIDOSIS, AND HYPERTENSION

Pseudohypoaldosteronism Type 2 (Gordon's Syndrome)

Gordon's syndrome is the clinical inverse of Gitelman's syndrome. It is an autosomal dominant condition characterized by hypertension, hyperkalemia, and mild hyperchloremic metabolic acidosis.

Pathogenesis

Two responsible genes have been identified.²⁸ They encode two members of the with-no-lysine kinase family: WNK1 and WNK4. The WNK kinases are both expressed in the kidney within the convoluted tubule and the collecting ducts.

WNK4 acts as a negative regulator of thiazide-sensitive Na⁺-Cl⁻ cotransporter (NCCT) function (see Fig 47.2), reducing cell surface expression of NCCT. WNK4 also downregulates the potassium channel ROMK and epithelial chloride flux.

Mutations in WNK4 are missense mutations and cause loss of function, so that WNK4 loses its ability to suppress NCCT and ROMK. Transporter overactivity consequently leads to sodium and potassium retention.

WNK1 prevents WNK4 from interacting with NCCT. Mutations in WNK1 are intronic deletions that increase WNK1

Aldosterone Biosynthesis Defects				
Defective enzyme	21-hydroxylase	3 β -hydroxysteroid dehydrogenase	Cholesterol desmolase	Aldosterone synthase
Incidence	Most common (1:11,000–23,000)	Rare	Rare	Rare
Aldosterone	Deficient	Deficient	Deficient	Deficient
Cortisol production	Deficient	Deficient	Deficient	Normal cortisol
ACTH	Loss of feedback inhibition	Loss of feedback inhibition	Loss of feedback inhibition	Normal feedback inhibition
Adrenal hyperplasia	Yes	Yes	Yes	No
Genital ambiguity	In females	In females	In females	No
Clinical features	Children with failure to thrive; hyponatremia, hyperkalemia, acidosis, and hypotension			
Elevated metabolites	17-Hydroxyprogesterone	Dehydroepiandrosterone	Dehydroepiandrosterone	Corticosterone
Therapy	Oral hydrocortisone and 9 α -fludrocortisone			9 α -fludrocortisone

Figure 47.13 Characteristics of diseases with aldosterone biosynthetic defects. ACTH, adrenocorticotrophic hormone.

expression. WNKs are intriguing targets for novel antihypertensive agents.

Clinical Manifestations and Diagnosis

Hyperkalemia may be present from birth, but as in GRA, hypertension may not be manifested until later in life. Patients show hyperchloremic metabolic acidosis; plasma renin and aldosterone are reduced to variable degrees.

Treatment

As specific inhibitors of the NCCT, thiazides are able to correct completely the clinical and biochemical features of Gordon's syndrome.

NEPHROGENIC DIABETES INSIPIDUS

Congenital nephrogenic diabetes insipidus (NDI) is a rare polyuric disorder identified by the failure to concentrate urine despite normal or elevated levels of vasopressin. Glomerular filtration rate (GFR) and solute excretion rate are normal. Congenital NDI is due to mutations in key proteins controlling water reabsorption in the distal tubule (see Fig. 47.5). Acquired diabetes insipidus is much more common, and its diagnosis and management are discussed in Chapter 8.

Pathogenesis

More than 90% of patients have X-linked recessive NDI with mutations in *AVPR2*, the gene at Xq28 coding for the arginine vasopressin receptor (AVPR). Mutant proteins are conformationally different, resulting in intracellular trapping of the receptor, which is retained in the endoplasmic reticulum. On occasion, the receptor may be expressed on the cell surface but is unable to bind vasopressin or to trigger an appropriate cyclic adenosine monophosphate (cAMP) response.²⁹ In less than 10% of the families, congenital NDI has an autosomal recessive inheritance, and mutations have been identified in the gene for aquaporin 2 located on chromosome 12q13. Similar to X-linked NDI, most autosomal recessive AQP2 mutations are held back in the endoplasmic reticulum. A rare autosomal dominant form of NDI, also caused by mutation in *AQP2*, has been reported. These mutations lead to mistransporting of AQP2 mutant proteins to the basolateral membrane instead of the apical membrane.³⁰ Reduced expression of AQP2 may result in acquired NDI secondary to lithium or demeclocycline therapy.

Clinical Features

Manifestations of congenital NDI appear within the first weeks of life. Males with *AVPR2* mutations have marked polyuria and excessive thirst, which is often not recognized in early infancy. Unless the condition is suspected early, children have recurrent episodes of severe hypernatremic dehydration, occasionally complicated by convulsions.³¹ Delayed development and mental retardation are possible consequences of these episodes. Cranial computed tomography may occasionally show dystrophic calcification in the basal ganglia and the cerebral cortex.

A reduced intake of calories because of the large quantities of water that are ingested leads to growth failure beginning in early childhood. Increased urine volumes may result in dilation of the lower urinary tract. Renal cortical damage, because of recurrent episodes of severe dehydration, may result in impairment of renal function. Heterozygous females may show variable degrees of

polyuria and polydipsia. The onset and severity of clinical features of autosomal recessive NDI are similar to those of the X-linked form.

Diagnosis

Episodes of dehydration are marked by hypernatremia, hyperchloremia, and occasionally elevated levels of urea and creatinine. Polyuria with low urine osmolality (<200 mOsm/kg) and hypernatremia with plasma Na⁺ concentration above 150 mmol/l and plasma osmolality above 300 mOsm/kg are highly suggestive of either vasopressin deficiency (central diabetes insipidus) or resistance to its action (NDI). Central diabetes insipidus is more common than NDI. Primary polydipsia resembles true diabetes insipidus in that compulsive water drinking results in polyuria with low urine osmolality; however, the plasma osmolality in primary polydipsia is normal or borderline low.

To confirm the lack of renal concentrating ability and to distinguish NDI from central diabetes insipidus and primary polydipsia, a vasopressin test is performed. Desamino-8-D-arginine vasopressin (DDAVP) is administered nasally (5 to 10 µg in neonates and infants, 20 µg in children) or by an intramuscular injection (0.4 to 1.0 µg in infants and young children, 2 µg in older children). Hourly urine collection is done during the next 6 hours. After administration of DDAVP, patients with NDI fail to show a rise of urine osmolality, from 200 to 300 mOsm/kg (normal, >800 mOsm/kg). Those with central diabetes insipidus and primary polydipsia concentrate urine appropriately.

Persistence of polyuria for years may result in a washout of the medullary countercurrent concentration mechanism. Several days of treatment with DDAVP may be required to elicit an appropriate response in these patients. In patients in whom the diagnosis of primary polydipsia is strongly suspected, supervised reduction of fluid intake during several days may restore normal sensitivity to DDAVP.

Differential Diagnosis

Patients with central diabetes insipidus show hypernatremia with inappropriately dilute urine, no primary renal disease, and a rise in urine osmolality after administration of vasopressin or its analogues. Central diabetes insipidus usually results from posterior pituitary neuronal damage, which may be secondary to tumors (craniopharyngioma, optic glioma, metastasis), Langerhans cell histiocytosis, trauma (e.g., fracture of base of skull), or infections (meningitis, encephalitis). Deficiency of vasopressin may also be familial, with an autosomal dominant inheritance. Mutations of *AVP-NP2*, the gene for vasopressin-neurophysin II, have been reported.³² The onset of vasopressin deficiency in the familial form may not be apparent until after the first few years of life. Central diabetes insipidus may also occur with the autosomal recessive syndrome of diabetes insipidus, diabetes mellitus, optic atrophy, and deafness (DIDMOAD, or Wolfram syndrome), which is autosomal recessive.

Many patients with central diabetes insipidus or NDI have a partial defect in vasopressin secretion or action. They are therefore able to concentrate urine to varying degrees after DDAVP administration, making precise diagnosis difficult. Measurement of plasma vasopressin in relation to plasma osmolality after an osmotic stimulus, such as fluid restriction, allows differentiation in these patients. Patients with severe or partial central diabetes insipidus always show subnormal vasopressin levels relative to

plasma osmolality. In contrast, the values from patients with NDI or psychogenic polydipsia are always within or above the normal range.

Magnetic resonance imaging of the brain produces a bright spot on T1-weighted images of the posterior pituitary in normal individuals and also those with NDI or primary polydipsia. This signal is absent in most patients with central diabetes insipidus.

The differential response of clotting factors and urine osmolality to DDAVP is useful in differentiating X-linked (*AVPR2* abnormalities) from autosomal recessive (*AQP2* mutations) NDI. Patients with *AQP2* abnormalities show normal increases in factor VIII and von Willebrand factor after DDAVP infusion; this response is absent in those with an *AVPR2* defect.^{31,33} Sequencing of *AVPR2* and *AQP2* is useful in identification of the molecular defect underlying NDI. Congenital NDI should also be differentiated from acquired forms of NDI (see Chapter 8).

Treatment

Appropriate management of patients with NDI prevents episodes of dehydration, allowing normal physical growth and development. Patients must have adequate water intake to prevent dehydration. The renal solute load is minimized by restriction of dietary protein and salt intake. Adequate energy and nutrients, depending on the age, should be provided to promote normal growth and development.

Thiazide diuretics, such as hydrochlorothiazide (1 to 2 mg/kg every 12 hours), when combined with reduction of salt intake, are effective in reducing urine output. Thiazides inhibit salt reabsorption in distal convoluted tubules, which leads to mild volume depletion. Hypovolemia stimulates fluid reabsorption in the proximal tubules, thereby diminishing water delivery to vasopressin-sensitive sites in the collecting ducts. The antipolyuric effect can be enhanced by combination therapy with amiloride (0.1 to 0.2 mg/kg every 8 to 12 hours).

Because prostaglandins normally antagonize the action of vasopressin, prostaglandin synthase inhibitors are also effective in reducing urine volume and free water clearance. Not all non-steroidal anti-inflammatory drugs are equally potent in inhibiting renal prostaglandin synthesis. Indomethacin (1 mg/kg every 12 hours) is most commonly used but may reduce GFR and cause gastrointestinal side effects.

Fanconi Syndrome and Other Proximal Tubule Disorders

John W. Foreman

The proximal tubule is responsible for the reabsorption of the bulk of a number of solutes, including glucose, amino acids, bicarbonate, and phosphate. A number of disorders, mainly heritable, that affect proximal tubule reabsorption are described in this chapter, but renal tubular acidosis and familial forms of hyperphosphaturia are discussed in Chapters 12 and 10, respectively.

Most nonelectrolyte solutes are reabsorbed in the proximal tubule through specific transport proteins that cotransport them in conjunction with sodium (Fig. 48.1). The driving force for this solute transport is the electrochemical gradient for sodium entry maintained by the enzyme $\text{Na}^+, \text{K}^+ \text{-ATPase}$. Most disorders of isolated solute reabsorption are related to defects in specific transport proteins, whereas disorders affecting multiple solutes, such as Fanconi syndrome, are probably secondary to defects in energy generation, $\text{Na}^+, \text{K}^+ \text{-ATPase}$ activity, or dysfunction of cellular organelles involved with membrane protein recycling.

FANCONI SYNDROME

Definition

In the 1930s, de Toni, Debré, and coworkers and Fanconi independently described several children with the combination of renal rickets, glycosuria, and hypophosphatemia. Fanconi syndrome nowadays refers to a global dysfunction of the proximal tubule leading to excessive urinary excretion of amino acids, glucose, phosphate, bicarbonate, and other solutes handled by this nephron segment. These losses lead to the clinical problems of acidosis, dehydration, electrolyte imbalance, rickets, osteomalacia, and growth failure. Numerous inherited or acquired disorders are associated with Fanconi syndrome (Fig. 48.2).

Etiology and Pathogenesis

The sequence of events leading to Fanconi syndrome is incompletely defined and probably varies with each cause. Possible mechanisms include widespread abnormality of most or all of the proximal tubule carriers, for example, a defect in sodium binding to the carrier or insertion of the carrier into the brush border membrane, “leaky” brush border membrane or tight junctions, inhibited or abnormal $\text{Na}^+, \text{K}^+ \text{-ATPase}$ pump, or impaired mitochondrial energy generation (see Fig. 48.1). An abnormality in energy generation has been implicated in a number of disorders, including hereditary fructose intolerance, galactosemia, mitochondrial cytopathies, and heavy metal poisoning as well as in a number of experimental models of Fanconi syndrome. Abnormal subcellular organelle function, such as the lysosome in cystinosis

or the megalin-cubilin endocytic pathway in Dent disease, is also a cause of Fanconi syndrome (Fig. 48.3).

In adults, the most common causes of persistent Fanconi syndrome are an endogenous or exogenous toxin such as a heavy metal, a medication, and a dysproteinemia; in children, the most common persistent cause is an inborn error of metabolism, such as cystinosis. Specific causes of Fanconi syndrome are discussed after a general description of the clinical manifestations and treatment of the syndrome.

Clinical Manifestations of Fanconi Syndrome

Fanconi syndrome gives rise to a number of abnormalities (Fig. 48.4).

Aminoaciduria

Aminoaciduria is a cardinal feature of Fanconi syndrome. Virtually every amino acid is found in excess in the urine, hence the term *generalized aminoaciduria*. There are, however, no clinical consequences because the losses are trivial in relation to the dietary intake.

Glycosuria

Glycosuria secondary to proximal tubule dysfunction is another of the cardinal features of Fanconi syndrome and occurs because of impaired tubular reabsorption of glucose. It is often one of the first diagnostic clues. Like aminoaciduria, it rarely causes symptoms.

Hypophosphatemia

Hypophosphatemia, secondary to impairment in phosphate reabsorption, is a common finding in Fanconi syndrome. Assessment of tubular phosphate handling can be made by measuring the maximum phosphate reabsorption in relation to the glomerular filtration rate (TmP/GFR) on fasting urine and blood samples. Elevated parathyroid hormone (PTH) and low vitamin D levels also may play a role in the phosphaturia of Fanconi syndrome, although these hormonal abnormalities are not always present. A few patients have impaired conversion of 25-hydroxyvitamin D to 1,25-hydroxyvitamin D; metabolic acidosis, another feature of Fanconi syndrome, may also impair this conversion. Another mechanism for the hypophosphatemia is impairment of the megalin-dependent reabsorption and degradation of filtered PTH.¹ Unabsorbed PTH then binds to receptors in more distal portions of the proximal tubule, leading to increased endocytosis of apical phosphate transporters and increased phosphaturia. The hypophosphatemia, especially if it is accompanied by hyperparathyroidism and low

Figure 48.1 Defects and potential defects in proximal tubular solute handling. Solute uptake by the brush border membrane from the lumen is coupled to Na^+ influx. The favorable electrochemical driving force for luminal Na^+ is maintained by the Na^+/K^+ -ATPase pump. Transported solute is then either used by the cell or returned to the blood across the basolateral membrane. Fanconi syndrome could arise because of a defect in one of six areas as shown. ATP, adenosine triphosphate.

Causes of Fanconi Syndrome	
Inherited Causes	
Cystinosis	
Galactosemia	
Hereditary fructose intolerance	
Tyrosinemia	
Wilson's disease	
Lowe syndrome	
Dent disease	
Glycogenosis	
Mitochondrial cytopathies	
Idiopathic	
Acquired Causes	
Drugs: <i>cisplatin, ifosfamide, tenofovir, cidofovir, adefovir, didanosine, gentamicin, azathiopurine, valproic acid (sodium valproate), suramin, streptozocin (streptozotocin), ranitidine</i>	
Dysproteinemias: <i>multiple myeloma, Sjögren's syndrome, light-chain proteinuria, amyloidosis</i>	
Heavy metal poisoning: lead, cadmium	
Other poisonings: Chinese herbal medicine, glue sniffing, diachrome	
Other: nephrotic syndrome, renal transplantation, acute tubular necrosis	

Figure 48.2 Causes of Fanconi syndrome. More common causes are shown in italics.

1,25-hydroxyvitamin D levels, often leads to significant bone disease, presenting with pain, fractures, rickets, or growth failure.

Hyperchloremic Metabolic Acidosis

Hyperchloremic metabolic acidosis, another feature of Fanconi syndrome, is a result of impaired bicarbonate reabsorption by the proximal tubule (proximal or type 2 renal tubular acidosis; see Chapter 12). This impaired reabsorption can lead to the loss

Figure 48.3 Megalin-cubilin endocytic pathway in proximal tubular cells. Low-molecular-weight proteins in the luminal fluid bind to the megalin-cubilin complex and are endocytosed. The recycling of megalin and further catabolism of these proteins are dependent on acidification of the vesicle by a proton pump. The CIC-5 chloride channel provides an electrical shunt for efficient functioning of the proton pump. This endocytosis pathway plays a role in membrane transporter recycling, and disruption of this pathway interferes with absorption of other luminal solutes.

of more than 30% of the normal filtered load of bicarbonate. As the serum bicarbonate concentration falls, the filtered load falls, and excretion drops such that the serum bicarbonate concentration usually remains between 12 and 18 mmol/L. On occasion, there is an associated defect in distal acidification, usually in association with long-standing hypokalemia or nephrocalcinosis. Ammoniogenesis is usually normal or increased because of the hypokalemia and acidosis, unless there is an associated impairment in GFR.

Natriuresis and Kaliuresis

Natriuresis and kaliuresis are common in Fanconi syndrome and can give rise to significant, even life-threatening problems. These electrolyte losses are in part related to impaired bicarbonate reabsorption, with the subsequent urinary excretion of sodium and potassium ions with the bicarbonate. In some cases, sodium and potassium losses are so great that metabolic alkalosis and hyperaldosteronism result, simulating Bartter syndrome despite the lowered bicarbonate threshold. The clearance of potassium may be twice that of the GFR, and the resulting hypokalemia can cause sudden death.

Polyuria and Polydipsia

Polyuria, polydipsia, and frequent bouts of severe dehydration are common symptoms in young patients with Fanconi syndrome. The polyuria is mainly related to the osmotic diuresis from the excessive urinary solute losses; but in some patients, there is an associated concentrating defect, especially in patients with prolonged hypokalemia.

Growth Retardation

Growth retardation in children with Fanconi syndrome is multifactorial. Hypophosphatemia, disordered vitamin D metabolism, and acidosis contribute to growth failure, as do chronic hypokalemia and extracellular volume contraction. Glycosuria and aminoaciduria probably do not play a role. However, even with correction of all these metabolic abnormalities, most patients fail to grow, especially those with cystinosis.

Hypouricemia

Hypouricemia, caused by impairment in renal handling of uric acid, is often present in Fanconi syndrome, especially in adults. Urolithiasis from the uricosuria has only rarely been reported, probably because the urine flow and pH are increased, inhibiting uric acid crystallization.

Proteinuria

Proteinuria is usually minimal, except when Fanconi syndrome develops in association with the nephrotic syndrome. Typically, only low-molecular-weight proteins (<30,000 daltons) are excreted, for example, enzymes, immunoglobulin light chains, and hormones.

Treatment of Fanconi Syndrome

Therapy, whenever possible, should be directed at the underlying causes (see later discussion), for example, avoidance of the offending nutrient in galactosemia, hereditary fructose intolerance, or tyrosinemia; treatment of Wilson's disease with penicillamine and other copper chelators; or treatment of heavy metal intoxication by chelation therapy. In these cases, resolution of Fanconi syndrome usually is complete.

In other instances, therapy is directed at the biochemical abnormalities secondary to the renal solute losses and at the bone disease that is often present in these patients. The proximal renal tubular acidosis usually requires large doses of alkali for correction. Some patients benefit from hydrochlorothiazide to minimize the volume expansion associated with these large doses of alkali. Potassium supplementation is also commonly needed, especially if there is a significant renal tubular acidosis. The use of potassium citrate, lactate, or acetate will correct not only the hypokalemia but also the acidosis. A few patients will require sodium supplementation along with potassium. Again, the use

of a metabolizable anion will aid in the correction of the acidosis. Rarely, patients may need sodium chloride supplementation. Usually, these patients have alkalosis when untreated as a result of large urinary sodium chloride losses, which lead to volume contraction that overrides the renal tubular acidosis. Magnesium supplementation may be required. Adequate fluid intake is essential. Correction of hypokalemia and its effect on the concentrating ability of the distal tubule may lessen the polyuria.

Bone disease is multifactorial, including hypophosphatemia, urinary loss of vitamin D-binding protein and vitamin D, decreased synthesis of calcitriol in some patients, hypercalciuria, and chronic acidosis. Hypophosphatemia should be treated with 1 to 3 g/day of oral phosphate with the goal of normalizing serum phosphate levels. Many patients will require supplemental vitamin D for adequate treatment of the rickets and osteomalacia. It is unclear whether standard vitamin D (calciferol [ergocalciferol]) or a vitamin D metabolite is better for supplementation. Currently, most clinicians use a vitamin D metabolite, such as 1,25-dihydroxycholecalciferol (calcitriol). These metabolites obviate the concern of inadequate vitamin D hydroxylation by the proximal tubule mitochondria and reduce the risk for prolonged hypercalcemia because of their shorter half-life. Vitamin D therapy will also improve the hypophosphatemia and lessen the risk for hyperparathyroidism. Supplemental calcium is indicated in those with hypocalcemia after supplemental vitamin D is started.

Hyperaminoaciduria, glycosuria, proteinuria, and hyperuricosuria usually do not lead to clinical difficulties and do not require specific treatment. Carnitine supplementation, to compensate for the urinary losses, may improve muscle function and lipid profiles, but the evidence is inconsistent.

INHERITED CAUSES OF FANCONI SYNDROME

Cystinosis

Definition

Cystinosis, or cystine storage disease, is characterized biochemically by excessive intracellular storage, particularly in lysosomes, of the amino acid cystine.² Three different types of cystinosis can be distinguished on the basis of the clinical course and the intracellular cystine content. Benign or adult cystinosis is associated with cystine crystals in the cornea and bone marrow only and the mildest elevation in intracellular cystine levels; there is no renal disease. Infantile or nephropathic cystinosis is the most common form and is associated with the highest intracellular levels of cystine and the earliest onset of renal disease. The intermediate or adolescent form has intracellular cystine levels in between those of the infantile and adult forms and later onset of renal disease.

Etiology and Pathogenesis

Nephropathic cystinosis is transmitted as an autosomal recessive trait localized to the short arm of chromosome 17, with an estimated incidence of 1 in 200,000 live births. The *CTNS* gene codes for a lysosomal membrane protein, cystinosisin, that mediates the transport of cystine from the lysosome.³ The benign and intermediate forms of cystinosis are also associated with mutations in this gene but still have some functional transport protein, leading to lower intracellular cystine levels and slower onset of renal disease in the intermediate form and no renal disease in the benign form.

Figure 48.5 Corneal opacities in cystinosis. Tinsell-like refractile opacities in the cornea of a patient with cystinosis under slit-lamp examination. (From reference 4.)

Clinical Manifestations

The first clinical symptoms and signs in nephropathic cystinosis are those of Fanconi syndrome and usually appear in the second half of the first year of life. Subtle abnormalities of tubular function can be demonstrated earlier in families with index cases, but there always is a delay between birth and the first symptoms. Rickets is common after the first year of life, along with growth failure. The growth failure occurs before the GFR declines and despite correction of electrolyte and mineral deficiencies. The GFR invariably declines and end-stage renal disease (ESRD) occurs by late childhood. Nephrocalcinosis is relatively common, and a few patients have developed renal calculi. Photophobia is another common symptom that occurs by 3 years of age and is progressive. Older patients with cystinosis may develop visual impairment and blindness. Children with cystinosis usually have fair complexions and blond hair, but dark hair has been observed in some. Cystinosis has been observed in other ethnic groups but is less common than in Caucasians. The diagnosis is based on the demonstration of elevated intracellular levels of cystine, usually in white blood cells or skin fibroblasts. Patients with nephropathic and intermediate cystinosis have intracellular cystine levels that exceed 2 nmol half-cystine/mg protein. Normal patients have levels that are less than 0.2 nmol half-cystine/mg protein. Heterozygotes for cystinosis will have levels that range from 0.2 to 1 nmol half-cystine/mg protein. A slit-lamp demonstration of corneal crystals is strongly suggestive of the diagnosis (Fig. 48.5).² A prenatal diagnosis can be made with amniocytes or chorionic villi.

Common late complications of cystinosis include hypothyroidism, splenomegaly and hepatomegaly, decreased visual acuity, swallowing difficulties, pulmonary insufficiency, and corneal ulcerations.⁵ Less commonly, older patients have developed insulin-dependent diabetes mellitus, myopathy, and progressive neurologic disorders. Decreased brain cortex has also been noted on imaging in some patients.

Pathology

The morphologic features of the kidney in cystinosis vary with the stage of the disease. Early in the disease, cystine crystals are present in tubular epithelial cells, interstitial cells, and rarely glomerular epithelial cells (Fig. 48.6A).^{6,7} A swan-neck deformity or thinning of the first part of the proximal tubule is an early finding but is not unique to cystinosis. Later, there is pronounced tubular atrophy, interstitial fibrosis, and abundant crystal deposition with giant cell formation of the glomerular visceral

Figure 48.6 Cystine crystals in the kidney in cystinosis. **A**, Crystals are seen in a photomicrograph of an alcohol-fixed nephrectomy specimen, taken through incompletely crossed polarizing filters. Birefringent crystals are evident in tubular epithelial cells and free in the interstitium. **B**, Electron micrograph of a renal biopsy specimen showing hexagonal, rectangular, and needle-shaped crystals in macrophages within the interstitium. (Original magnification $\times 3000$.) (**A** from reference 6; **B** from reference 7.)

epithelium, segmental sclerosis, and eventual glomerular obsolescence. Electron microscopy studies have demonstrated intracellular crystalline inclusions consistent with cystine (Fig. 48.6B). Peculiar “dark cells,” unique to the cystinotic kidney, have also been observed.

Treatment

Nonspecific therapy for infantile cystinosis consists of vitamin D therapy and replacement of the urinary electrolyte losses, followed, in due course, by the management of the progressive renal failure (Fig. 48.7). Cysteamine has now been shown to lower tissue cystine and to slow the decline in GFR, especially in children with a normal serum creatinine concentration treated before 2 years of age (Fig. 48.8).⁸ Cysteamine therapy also improves linear growth but not Fanconi syndrome. The most common problems associated with cysteamine therapy are nausea, vomiting, and a foul odor and taste. Treatment should begin with a low dose of cysteamine soon after the diagnosis is made, increased during 4 to 6 weeks to 60–90 mg/kg/day in four divided doses as close to every 6 hours as possible. Slowly increasing the dose minimizes the risk for a serum sickness-like reaction. Leukocyte cystine levels should be checked every 3 to 4 months to monitor effectiveness and compliance, with the goal of achieving and maintaining a cystine level of below 2.0 and

preferably below 1.0 nmol half-cystine/mg protein. A 50-mM solution of cysteamine applied topically onto the eye has proved useful in depleting the cornea of cystine crystals but requires administration 6 to 12 times a day to be effective.

Treatment of ESRD in these children poses no greater problems than in other children. Successful renal transplantation reverses the renal failure and Fanconi syndrome but does not appear to improve the extrarenal manifestations of cystinosis. Cysteamine therapy should be continued after transplantation. Cystine does not accumulate in the transplanted kidney, except in infiltrating immunocytes.

Galactosemia

Etiology and Pathogenesis

Galactosemia is an autosomal recessively inherited disorder of galactose metabolism. It is most commonly the result of deficient

activity of the enzyme galactose 1-phosphate uridyltransferase; this occurs with an incidence of 1 in 62,000 live births.⁹ Deficiency of this enzyme leads to the intracellular accumulation of galactose 1-phosphate, with damage to the liver, proximal renal tubule, ovary, brain, and lens. A less frequent cause of galactosemia is a deficiency of galactose kinase, which forms galactose 1-phosphate from galactose. Cataracts are the only manifestation of this form of galactosemia. The pathogenesis of the symptoms of galactosemia is not clear. Accumulation of galactose 1-phosphate subsequent to the ingestion of galactose can inhibit a number of pathways for carbohydrate metabolism, and there is some correlation of its level with clinical symptoms. Defective galactosylation of proteins has also been postulated. Formation of galactitol from galactose by aldose reductase has been proposed as a pathogenetic mechanism, and this is probably responsible for the cataract formation.

Clinical Manifestations

Affected infants ingesting milk containing lactose, the most common source of galactose in the diet, rapidly develop vomiting, diarrhea, and failure to thrive. Jaundice from unconjugated hyperbilirubinemia is common, along with severe hemolysis. Continued intake of galactose leads to hepatomegaly and cirrhosis. Cataracts appear within days after birth, although at first they often are detectable only with a slit lamp. Mental retardation may develop within a few months. Fulminant *Escherichia coli* sepsis has been described in a number of infants; it may be a consequence of inhibited leukocyte bactericidal activity.

In addition to these clinical findings, galactose intake leads within days to hyperaminoaciduria and albuminuria. Raised urine sugar excretion is principally a result of galactosuria and not glycosuria. There seems to be little or no impairment in glucose handling by the renal tubule. Galactosemia should be suspected whenever there is a urinary reducing substance that does not react in a glucose oxidase test. The diagnosis can be confirmed by demonstration of deficient transferase activity in red blood cells, fibroblasts, leukocytes, or hepatocytes.

Treatment

Galactosemia is treated by elimination of galactose from the diet. Acute symptoms and signs resolve in a few days. Cataracts will also regress to some extent. However, even with early elimination of galactose, a common outcome in galactosemia is developmental delay, speech impairment, ovarian dysfunction, and growth retardation. Profound intellectual deficits are rare even in infants treated late.

Treatment of Cystinosis	
Problem	Therapy
Removal of lysosomal cystine	Cysteamine, 0.325 g/m ² q 6hr to maintain leukocyte cystine level <1 nmol half-cystine*/mg protein
Correction of Tubulopathy	
Dehydration	2–6 l/d fluid
Acidosis	2–15 mmol/kg/d K ⁺ citrate
Hypophosphatemia	1–4 g/d K ⁺ phosphate
Rickets	0.25–1 µg/d calcitriol
Adjunct therapies	NaCl, carnitine, indomethacin, hydrochlorothiazide
Later Therapies	
Growth failure	Growth hormone
Hypothyroidism	Thyroxine
Renal failure	Renal replacement therapy, ideally renal transplantation

Figure 48.7 Treatment of cystinosis. *By convention, units are half-cystine because the cystine originally was converted to two cysteine molecules, or “broken in half,” before measurement.

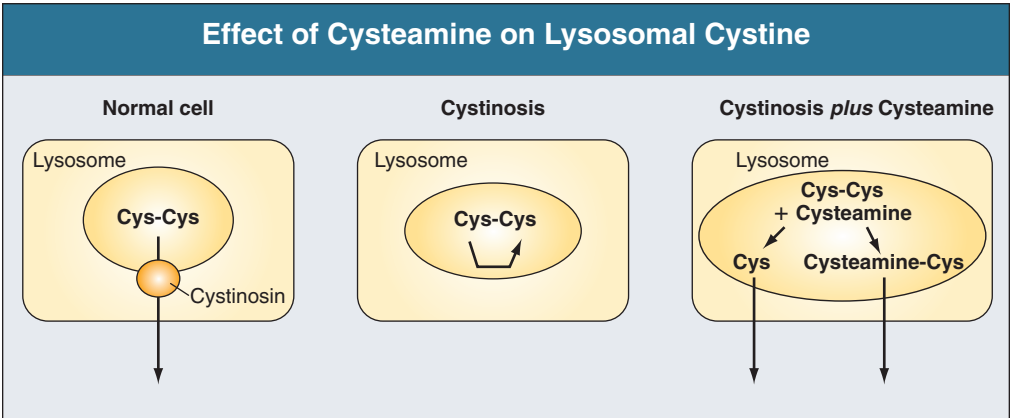

Figure 48.8 Effect of cysteamine on lysosomal cystine. In cystinosis, the transporter (cystinosin) for cystine (Cys-Cys) egress from the lysosome is defective. Cysteamine can easily enter the lysosome and combine with cystine, forming cysteine (Cys) and the mixed disulfide cysteamine-cysteine. Both of these compounds can exit the lysosome through a transporter other than the cystine carrier.

Hereditary Fructose Intolerance

Etiology and Pathogenesis

Hereditary fructose intolerance is another disorder of carbohydrate metabolism associated with Fanconi syndrome.¹⁰ It is inherited as an autosomal recessive trait with an incidence estimated to be 1 in 20,000. It is caused by a deficiency of the B isoform of the enzyme fructose 1-phosphate aldolase, which cleaves fructose 1-phosphate into D-glyceraldehyde and dihydroxyacetone phosphate. Deficient activity of aldolase B leads to tissue accumulation of fructose 1-phosphate and reduced levels of ATP.

Clinical Manifestations

Symptoms of hereditary fructose intolerance appear at weaning when fruit, vegetables, and sweetened cereals that contain fructose or sucrose are introduced. Children with this disorder experience nausea, vomiting, and symptoms of hypoglycemia shortly after ingestion of fructose, sucrose, or sorbitol. These symptoms may progress to convulsions, coma, and even death, depending on the amount consumed. Young infants, when they are exposed to fructose, may have a catastrophic illness, with severe dehydration, shock, acute liver impairment, bleeding, and acute kidney injury. Concomitant serum biochemical findings after fructose ingestion are a fall in glucose, phosphate, and bicarbonate and a rise in uric acid and lactic acid. Chronic exposure to fructose leads to failure to thrive, hepatomegaly, jaundice, hepatic cirrhosis, and nephrocalcinosis. Children with hereditary fructose intolerance learn to avoid sweets and as a result have few dental caries.

Diagnosis

The diagnosis should be suspected when symptoms develop after the ingestion of fructose. Confirmation can be made either by a carefully applied fructose tolerance test or by assaying the activity of fructose 1-phosphate aldolase in a liver biopsy specimen.

Treatment

Treatment involves strict avoidance of foods containing fructose and sucrose, but because most patients develop a strong aversion to such foods, this is usually easy. The greatest risk occurs during infancy before affected individuals learn to avoid fructose.

Glycogenosis

Most patients with glycogen storage disease and Fanconi syndrome have an autosomal recessive disorder characterized by heavy glycosuria and increased glycogen storage in the liver and kidney, known as the Fanconi-Bickel syndrome, or glucose-losing syndrome, because the glucose losses can be massive.¹¹ The defect is deficient activity of the sugar transporter GLUT2 (see Fig. 48.10). GLUT2 facilitates sugar exit from the basolateral side of the proximal tubule and intestinal cell and sugar entry and exit from the hepatocyte and pancreatic β -cell. A few patients with type I glycogen storage disease have mild Fanconi syndrome but not Fanconi-Bickel syndrome. The therapy for this disorder is directed at the renal solute losses, treatment of rickets (which can be severe), and frequent feeding to prevent ketosis. Uncooked corn starch has been shown to lessen the hypoglycemia and to improve growth.

Tyrosinemia

Definition

Hereditary tyrosinemia type I, also known as hepatorenal tyrosinemia, is a defect of tyrosine metabolism affecting the liver, kidneys, and peripheral nerves.¹²

Etiology and Pathogenesis

The cause of hereditary tyrosinemia type I is a deficiency of fumarylacetoacetate hydrolase (FAH) activity; it is an autosomal recessive disorder. Decreased or absent FAH activity leads to accumulation of maleylacetoacetate (MAA) and fumarylacetoacetate (FAA) in affected tissues. These compounds can react with free sulfhydryl groups, reduce intracellular levels of glutathione, and act as alkylating agents. MAA and FAA are not detectable in plasma or urine but are converted to succinylacetoacetate and succinylacetone. Succinylacetone is structurally similar to maleic acid, a compound that causes Fanconi syndrome experimentally in rats and may be the cause of Fanconi syndrome in humans affected with tyrosinemia.

Clinical Manifestations

The liver is the major organ affected, and this may be evident as early as the first month of life. Such infants usually have severe disease and die in the first year of life. All children will eventually develop macronodular cirrhosis, and many develop hepatocellular carcinoma. Acute, painful peripheral neuropathy and autonomic dysfunction can also occur in tyrosinemia. Proximal renal tubular dysfunction is evident in all patients with tyrosinemia, especially those presenting after infancy. Nephromegaly is very common, and nephrocalcinosis may be seen. Glomerulosclerosis and impaired GFR may be seen with time.

Diagnosis

The diagnosis should be suspected with elevated plasma tyrosine and methionine levels together with their *p*-hydroxy metabolites. The presence of succinylacetone in blood or urine is diagnostic of hereditary tyrosinemia type I.

Treatment

The institution of a diet low in phenylalanine and tyrosine dramatically improves the renal tubular dysfunction. Nitisinone, which inhibits the formation of MAA and FAA, dramatically improves the renal and hepatic dysfunction.¹² Liver transplantation has been successfully used to treat patients with severe liver failure and to prevent the development of hepatocellular carcinoma. Liver transplantation leads to rapid correction of Fanconi syndrome.

Wilson's Disease

Definition

Wilson's disease is an inherited disorder of copper metabolism that affects numerous organ systems.^{13,14} It has an overall incidence of 1 in 30,000. About 40% of patients present with liver disease, 40% with extrapyramidal symptoms, and 20% with psychiatric or behavioral abnormalities.

Etiology and Pathogenesis

Wilson's disease is a defect in the P-type copper-transporting ATPase ATP7B, which is highly expressed in the liver, kidney, and placenta. It impairs biliary copper excretion and the incorporation of copper into ceruloplasmin. These abnormalities cause excessive intracellular accumulation of copper in the liver,

with subsequent overflow into other tissues such as brain, cornea, and renal proximal tubule.

Clinical Manifestations

Excessive storage of copper in the kidney leads to renal tubular dysfunction in most patients and full-blown Fanconi syndrome in some. Hematuria also has been noted. Renal plasma flow and GFR decrease as the disease progresses, but death from extrarenal causes occurs before the onset of renal failure. Fanconi syndrome usually appears before the onset of hepatic failure. Hypercalciuria with the development of renal stones and nephrocalcinosis also have been reported. Besides proximal tubular dysfunction, abnormalities in distal tubular function, decreased concentrating ability, and distal renal tubular acidosis have also been observed. Neurologic abnormalities, such as dysarthria and gait disturbances, may be the presenting symptom in young adults with Wilson's disease. Kayser-Fleischer rings, dense brown copper deposits around the iris, may be visible but typically can be seen only with a slit lamp.

Pathology

On histologic examination, the kidney in untreated Wilson's disease shows either no alteration on light microscopy or only some flattened proximal tubular cells without recognizable brush borders. Electron microscopy shows loss of the brush border, disruption of the apical tubular network, electron-dense bodies probably representing metalloproteins in the subapical region of tubule cell cytoplasm, and cavitation of the mitochondria with disruption of the normal cristae pattern. Rubeanic acid staining shows intracytoplasmic copper granules. The copper content of kidney tissue is markedly elevated.

Diagnosis

The diagnosis of Wilson's disease should be suspected in children and young adults with unexplained neurologic disease, chronic active hepatitis, acute hemolytic crisis, behavioral or psychiatric disturbances, or the appearance of Fanconi syndrome. In such patients, the presence of Kayser-Fleischer rings is an important clue in making the diagnosis. Serum ceruloplasmin levels are decreased in 96% of patients with Wilson's disease. A markedly increased urinary copper level is also useful in making the diagnosis, especially if it increases significantly with D-penicillamine. Liver copper levels are increased in untreated patients.

Treatment

Treatment with penicillamine, 1 to 1.5 g/day, reverses the renal dysfunction and may reverse the hepatic and neurologic disease, depending on the degree of damage before the onset of therapy. Recovery, however, is quite slow. Trientine can also chelate copper and is indicated in patients who cannot tolerate penicillamine. Tetrathiomolybdate is a potent agent in removing copper from the body and has been used in some patients with neurologic disease to prevent the immediate worsening of symptoms that can occur with penicillamine. Zinc salts, which induce intestinal metallothionein and blockade of intestinal absorption of copper, are useful in maintenance therapy. Liver transplantation has been successful in some patients but should be reserved for those with liver failure.

Lowe Syndrome

Lowe syndrome (oculocerebrorenal syndrome) is characterized by congenital cataracts and glaucoma, severe mental retardation,

hypotonia with diminished or absent reflexes, and renal abnormalities.^{15,16} Fanconi syndrome is followed by progressive renal impairment. ESRD usually does not occur until the third to fourth decade of life.

Lowe syndrome is transmitted as an X-linked recessive trait. Despite this inheritance pattern, Lowe syndrome has occurred in a few females. The defective gene codes for inositol polyphosphate 5-phosphatase, OCRL1, involved with cell trafficking and signaling.

Light microscopy of the kidney is normal early in the disorder, with endothelial cell swelling and thickening and splitting of the glomerular basement membrane seen by electron microscopy. In the proximal tubule cells, there is shortening of the brush border and enlargement of the mitochondria, with distortion and loss of the cristae. Only symptomatic treatment is available.

Dent Disease

Definition

Dent disease is an X-linked recessive disorder characterized by low-molecular-weight proteinuria, hypercalciuria, nephrolithiasis, nephrocalcinosis, and rickets.¹⁷⁻¹⁹ In addition, affected males often have aminoaciduria, phosphaturia, and glycosuria. Renal failure is common and may occur by late childhood. Hemizygous females usually have only proteinuria and mild hypercalciuria. X-linked recessive nephrolithiasis and X-linked recessive hypophosphatemic rickets have similar features, and most have a defect in the renal ClC-5 chloride channel. Dent disease type 2 is a clinically similar disease affecting males, but there is a mutation in the same gene that causes Lowe syndrome, although they do not have the brain or eye involvement seen in Lowe syndrome.¹⁷

Etiology and Pathogenesis

Most of these disorders are caused by a mutation in the *CLCN5* gene leading to inactive ClC-5 chloride channel function (see Fig. 48.3). The ClC-5 chloride channel spans the membrane of pre-endocytic vesicles just below the brush border of the proximal tubule. There it facilitates the entry of Cl⁻ that is necessary for the active acidification of the vesicles by a proton pump. Lack of this Cl⁻ channel interferes with protein reabsorption from the tubule through the megalin-cubilin receptor system and cell surface receptor recycling, which may explain the phosphaturia, glycosuria, and aminoaciduria.

The defective OCRL1 in Dent disease type 2 patients interferes with normal cell protein trafficking. The renal disease is typical of Dent disease, without the eye and brain disease seen in Lowe syndrome.

Filtered PTH is also reabsorbed by the megalin-cubilin system for degradation in the lysosome. Decreased PTH reabsorption allows increased binding to luminal PTH receptors and increased endocytosis of luminal phosphate transporters, leading to increased phosphaturia.¹

Mitochondrial Cytopathies

Definition

Mitochondrial cytopathies are a diverse group of diseases with abnormalities in mitochondrial DNA that lead to mitochondrial dysfunction in various tissues.²⁰

Clinical Manifestations

Most of the mitochondrial cytopathies present with neurologic disorders such as myopathy, myoclonus, ataxia, seizures, external

Mitochondrial Cytopathies
MERRF: myoclonic epilepsy with ragged red fibers
NARP: neuropathy, ataxia, and retinitis pigmentosa
MELAS: mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes
LHON: Leber's hereditary optic neuropathy
Leigh disease: maternally inherited Leigh disease (somnolence, blindness, deafness, peripheral neuropathy, degeneration of brainstem)
Pearson's syndrome: pancytopenia, exocrine pancreatic deficiency, hepatic dysfunction
Kearns-Sayre syndrome: ophthalmoplegia, pigmentary retinopathy, heart block, ataxia
Alpers' disease: intractable epilepsy, liver disease, neuronal degeneration

Figure 48.9 Mitochondrial cytopathies.

ophthalmoplegia, stroke-like episodes, and optic neuropathy. Other manifestations include retinitis pigmentosa, diabetes mellitus, exocrine pancreatic insufficiency, sideroblastic anemia, sensorineural hearing loss, pseudo-obstruction of the colon, hepatic disease, cardiac conduction disorders, and cardiomyopathy. These various manifestations tend to group together in specific syndromes and reflect specific mutations in mitochondrial DNA (Fig. 48.9).

The most common renal manifestation associated with mitochondrial cytopathies is Fanconi syndrome, although a number of patients have been described with focal segmental glomerulosclerosis and corticosteroid-resistant nephrotic syndrome. All the patients with renal abnormalities have had extrarenal disorders, mainly neurologic disease. Most patients present in the first months of life and die soon afterward.

Diagnosis

A clue to these disorders is elevated serum or cerebrospinal fluid lactate levels, especially in association with an altered lactate to pyruvate ratio, suggesting a defect in mitochondrial respiration. The presence of “ragged red fibers,” a manifestation of abnormal mitochondria, in a muscle biopsy specimen is another clue, especially with large abnormal mitochondria on electron microscopy of muscle tissue.

Treatment

There is little to offer these patients in terms of definitive therapy. Low mitochondrial enzyme complex III activity can be treated with menadione or ubidecarenone. Deficient mitochondrial enzyme complex I activity may be treated with riboflavin and ubidecarenone. Ascorbic acid has been used to minimize oxygen free radical injury. High-lipid, low-carbohydrate diet has been tried in cytochrome c oxidase deficiency.

Idiopathic Fanconi Syndrome

A number of patients develop the complete Fanconi syndrome in the absence of any known cause. Traditionally, these cases have been called adult Fanconi syndrome because it was thought that only adults were affected. However, it is clear that children may be affected, and a more proper designation is idiopathic

Fanconi syndrome. Not all of the features of Fanconi syndrome may be present when the patients are first seen, but they do appear with time. Idiopathic Fanconi syndrome can be inherited in an autosomal dominant, autosomal recessive, or even X-linked pattern. However, most cases occur sporadically, without any evidence of genetic transmission. The prognosis is quite variable, and some develop chronic renal failure 10 to 30 years after the onset of symptoms. A few patients have undergone renal transplantation; in some of these, Fanconi syndrome has recurred in the allograft without evidence of rejection, suggesting an extra-renal cause of the idiopathic Fanconi syndrome. In one family, the gene defect was localized to chromosome 15.²¹

Renal morphologic descriptions of such cases are scanty. In some reports, no abnormalities were found, and in others, tubular atrophy with interstitial fibrosis was interspersed with areas of tubular dilation. Markedly dilated proximal tubules with swollen epithelium and grossly enlarged mitochondria with displaced cristae have also been noted.

ACQUIRED CAUSES OF FANCONI SYNDROME

Numerous substances can injure the proximal renal tubule (see Fig. 48.2), and this injury can range from an incomplete Fanconi syndrome to acute tubular necrosis or ESRD. The extent of the tubular damage is quite variable and is dependent on the type of toxin, the amount ingested, and the host. A careful history of possible toxin exposure and recent medications is important in patients with tubular dysfunction. The more common causes of acquired Fanconi syndrome are identified in Figure 48.2.

Heavy Metal Intoxication

A major cause of proximal tubular dysfunction is heavy metal intoxication, principally lead²² and cadmium.²³ In lead poisoning, the renal tubular dysfunction, mainly aminoaciduria and mild glycosuria and phosphaturia, is usually overshadowed by the involvement of other organs, especially the central nervous system. Fanconi syndrome associated with cadmium poisoning is associated with severe bone pain, giving rise to the name *itai-itai* (“ouch-ouch”) disease for its occurrence in Japanese patients affected by industrial contamination of the soil.

Tetracycline

Outdated tetracycline causes a reversible Fanconi syndrome even in therapeutic doses. Recovery is rapid when the degraded drug is stopped. The compound responsible for the tubule dysfunction is anhydro-4-tetracycline formed from tetracycline by heat, moisture, and low pH.

Cancer Chemotherapy Agents

A number of cancer chemotherapy agents have been associated with Fanconi syndrome and renal tubular dysfunction, especially cisplatin²⁴ and ifosfamide.²⁵ Carboplatin has been associated with reduced GFR and magnesium wasting but not Fanconi syndrome. The nephrotoxicity of both cisplatin and ifosfamide is dose dependent and often irreversible. Besides the usual manifestations of Fanconi syndrome, cisplatin toxicity is characterized by hypomagnesemia, caused by hypermagnesuria, which can be extremely severe, persistent, and difficult to treat. Ifosfamide is more commonly associated with hypophosphatemic rickets.

Chloroacetaldehyde, a metabolite of ifosfamide, appears experimentally to cause Fanconi syndrome. Both ifosfamide and cisplatin can cause an irreversible reduction in GFR.

Other Drugs and Toxins

Exposure to a wide range of toxins may give rise to Fanconi syndrome, often in association with a reduced GFR, including methyl-3-chromone (diachrome), 6-mercaptopurine, toluene (glue sniffing), and Chinese herbal medicines containing an *Aristolochia* species.²⁶ There have also been anecdotal reports associating Fanconi syndrome with valproic acid (valproate), suramin, Lysol (a cresol-based antiseptic), gentamicin, and ranitidine. Antiviral²⁷ medications, especially antiretroviral agents, are an increasingly common cause of Fanconi syndrome.

Dysproteinemias

Dysproteinemia²⁸ from multiple myeloma, light-chain proteinuria,²⁹ Sjögren's syndrome, and amyloidosis is sometimes associated with Fanconi syndrome, which appears to be correlated with urinary free light chains with specific physicochemical characteristics that crystallize within the tubular cells.

Glomerular Disease

Nephrotic syndrome has rarely been associated with Fanconi syndrome. Most of these patients have focal segmental glomerulosclerosis, and the occurrence of Fanconi syndrome heralds a poor prognosis.

After Acute Kidney Injury

Tubular dysfunction during recovery from acute kidney injury from any cause can occur, whether or not a known tubular toxin was originally implicated.

After Renal Transplantation

Fanconi syndrome has appeared rarely after renal transplantation. The pathogenesis probably is multifactorial, for example, sequelae of acute tubular necrosis, rejection, nephrotoxic drugs, ischemia from renal artery stenosis, and residual hyperparathyroidism.

FAMILIAL GLUCOSE-GALACTOSE MALABSORPTION AND HEREDITARY RENAL GLYCOSURIA

Definition

Renal glycosuria refers to the appearance of readily detectable glucose in the urine when the plasma glucose concentration is in a normal range. When the plasma glucose concentration is in a physiologic range, virtually all the filtered glucose is reabsorbed in the proximal tubule.³⁰ Filtered glucose enters the proximal tubule through two specific carriers (SGLT1 and SGLT2) coupled to sodium and exits the cell through the sugar transporters GLUT1 and GLUT2 (Fig. 48.10). However, when the plasma level exceeds the physiologic range, the filtered load exceeds the capacity of these carriers, and glucose begins to appear in the urine; this is termed the renal threshold.

Figure 48.10 Proximal tubule glucose reabsorption. Glucose enters the proximal tubule cell coupled to Na^+ reabsorption from the lumen through a high-capacity, low-affinity transporter (SGLT2) in the early proximal tubule and a low-capacity, high-affinity transporter (SGLT1) in the late proximal tubule. Glucose exits the cell through the transporters GLUT1 and GLUT2 located in the late and early proximal tubule, respectively.

Etiology and Pathogenesis

Familial glucose-galactose malabsorption is a rare autosomal disorder that is due to mutations in the gene coding for the brush border sodium-glucose cotransporter SGLT1, which is found in the intestinal cell and the S₃ segment of the proximal renal tubule cell. The disorder is characterized by the neonatal onset of life-threatening diarrhea from the intestinal malabsorption of glucose and galactose that resolves rapidly with the removal of glucose and galactose and its dipeptide, lactose, from the diet. These patients frequently also have a mild renal glycosuria.

Hereditary renal glycosuria occurs with an incidence of 1 in 20,000 and appears to be inherited as a codominant trait with variable penetrance.³¹ This disorder is due to mutations in SGLT2 glucose transporter found in the early portion of the proximal tubule. Renal glycosuria has been divided into three types based on the reabsorption patterns observed during glucose infusion studies (Fig. 48.11). In type A, there is lowering of both the threshold and the maximal rate of tubular reabsorption of glucose. In type B, the maximal rate of glucose reabsorption is normal, but the threshold is low, and there is exaggerated splay in the tubular reabsorption versus filtered load curve. In type 0, there is virtually no reabsorption of filtered glucose, with the clearance of glucose nearly the same as that of inulin.³² This typing system has been called into question because clearance data suggest that patients with renal glycosuria have rates of glucose reabsorption that vary from virtually no reabsorption to

Figure 48.11 Renal glucose titration curves. The observed normal reabsorption curve follows the theoretical renal tubular glucose reabsorption until near the maximal reabsorption rate, when the observed rate deviates from the theoretical rate (splay). The point of deviation is the threshold. Stylized titration curves for types A, B, and O renal glycosuria are shown. (Modified from reference 32.)

nearly normal rates, rather than three distinct types, probably reflecting different mutations in the *SLC5A2* gene.³²

Natural History

Patients with familial glucose-galactose malabsorption appear to grow and develop normally with removal of the offending sugars from the diet. The clinical course of hereditary renal glycosuria is benign, except for a few patients with polyuria, and it is not a precursor to diabetes mellitus. Patients need to be aware of the condition in order not to receive unnecessary diagnostic investigations or even treatment for presumed diabetes mellitus.

AMINOACIDURIAS

Like glucose, amino acids are nearly completely reabsorbed in the proximal tubule by a series of specific carriers. A number of inherited disorders resulting in the incomplete reabsorption of a specific amino acid or a group of amino acids have been described (Fig. 48.12).^{33,34}

Cystinuria

Definition

Cystinuria is characterized by the excessive urinary excretion of cystine and the dibasic amino acids ornithine, lysine, and arginine.³⁵

Etiology and Pathogenesis

These four amino acids share a transport system on the brush border membrane of the proximal tubule. Because of the relative insolubility of cystine when its urine concentration exceeds 250 mg/l (1 mmol/l), patients with cystinuria have recurrent renal calculi.

Inherited Aminoacidurias		
Disease	Clinical Findings	Urine Amino Acids
Cystinuria	Urolithiasis	Cystine, lysine, ornithine, arginine
Hartnup disease	Rash, neurologic disease	Neutral amino acids
Iminoglycinuria	None	Proline, hydroxyproline, glycine
Lysinuric protein intolerance	Hyperammonemia, vomiting, diarrhea	Dibasic amino acids

Figure 48.12 Inherited aminoacidurias.

Cystinuria is an autosomal recessive trait with a disease incidence of 1 in 15,000.³⁵ Initially, there appeared to be three genetic types on the basis of *in vitro* studies of intestinal transport and amino acid excretion in heterozygotes. More recently, two genes (*SLC3A1* and *SLC7A9*) have been identified that are defective in cystinuria. *SLC3A1* heterozygotes have normal excretion rates for cystine. *SLC7A9* heterozygotes have cystine excretion rates that range from normal to nearly that of homozygous patients. On the basis of these data, a new classification has been proposed. Type A involves mutations in both *SLC3A1* genes, and type B mutations in *SLC7A9*.³⁶ Type AB is compound heterozygote. Type A accounts for 38% of cystinuria patients, type B for 47%, and type AB for 14%.

Clinical Manifestations

Cystine stones are typically yellow-brown (Fig. 48.13A) and are radiopaque (Fig. 48.13B). Cystine crystals appear as microscopic, flat hexagons in the urine (Fig. 48.13C), and this is a clue to the diagnosis.

Diagnosis

Patients can be screened for cystinuria with the cyanide-nitroprusside test, but type B heterozygotes may also give a positive result. The definitive test is to quantify cystine and dibasic amino acid excretion in a 24-hour urine specimen. Homozygotes excrete more than 118 mmol cystine/mmol creatinine (250 mg/g).

Treatment

The aim of therapy in cystinuria is to lower the urine cystine concentration to below 300 mg/l (1.25 mmol/l). The first step is to increase fluid intake. However, because most patients with cystinuria excrete 0.5 to 1 g/day of cystine, a urine output of 2 to 4 l/day is needed to achieve this goal. Cystine solubility increases in alkaline urine, but the urine pH must be above 7.5 to be effective. In patients with recurrent stone disease, thiols, such as penicillamine, are extremely useful through the formation of a more soluble mixed disulfide of the thiol and cysteine from cystine. The thiols also reduce the overall excretion of cystine through an unknown mechanism. Penicillamine should be started at 250 mg/day and gradually increased (maximum, 2 g/day) during 3 months to achieve a urine cystine concentration below 300 mg/l in conjunction with a high fluid intake. Tiopronin is equally effective and is better tolerated than penicillamine. It should also be started at a low dose and slowly increased (maximum, 2 g/day). Captopril can be useful (an effect resulting

Figure 48.13 Cystinuria. **A**, Both rough and smooth cystine calculi. **B**, Plain radiograph of a cystine calculus in the right renal pelvis and further multiple parenchymal calculi. **C**, Urine microscopy showing characteristic flat hexagonal crystals (see also Fig. 4.7G).

from its thiol structure, not its angiotensin-converting enzyme inhibitor effect), but the dose range (75 to 150 mg/day) may be limited by its hypotensive effects.

Hartnup Disease

Hartnup disease is an autosomal recessive trait characterized by a neutral aminoaciduria that arises from a defect in a specific carrier for neutral amino acid transport present in both the intestine and the proximal renal tubule. The gene responsible for Hartnup disease is *SLC6A19*. It codes for the neutral amino acid transporter B⁰AT1. From newborn screening programs, the genetic defect is more common than originally thought because most individuals with the aminoaciduria never manifest any symptoms. Individuals who become symptomatic with Hartnup disease have pellagra-like clinical features, including a photosensitive dermatitis, ataxia, and psychotic behavior. These symptoms appear to be secondary to niacin deficiency that is in part due to inadequate intestinal absorption of tryptophan, the precursor for niacin synthesis. However, most individuals who inherit the Hartnup transport defect do not have symptoms, so there must be other environmental or genetic factors that contribute to disease. Nicotinamide supplementation leads to clearing of the skin disease and, on occasion, some of the neurologic problems. The renal loss of neutral amino acids appears to have little clinical importance.

Iminoglycinuria

Iminoglycinuria is a benign heritable defect in the proximal tubule transporter PAT1, leading to incomplete reabsorption of proline, hydroxyproline, and glycine.

Lysinuric Protein Intolerance

Lysinuric protein intolerance is associated with recurrent bouts of hyperammonemia after a protein load, resulting from the decreased renal and intestinal dibasic amino acid transport.

Other Aminoacidurias

Rare individuals have been described with abnormalities in the excretion of other amino acids. These usually occur in association with mental retardation.

HEREDITARY DEFECTS IN URIC ACID HANDLING

Hereditary Renal Hypouricemia

Hereditary renal hypouricemia is a rare autosomal recessive disorder characterized by very low serum uric acid levels (<2.5 mg/dl [$<150 \mu\text{mol/l}$] in adult men and <2.1 mg/dl [$<124 \mu\text{mol/l}$] in adult women) and increased uric acid clearance, ranging from 30% to 150% of the filtered load.³⁷ In the normal kidney, uric acid is both reabsorbed and secreted in the proximal tubule by two different uric acid–anion exchange transporters and a voltage-sensitive pathway. In some patients, the defect is in the gene *SLC22A12* that codes for the protein URAT1; other patients have been found to have mutations in *SLC2A9* (GLUT9). Most patients do not have symptoms and are found incidentally when a low serum uric acid concentration is noted during routine serum chemistry evaluation. About one fourth of patients with renal hypouricemia have had renal stones, but only one third of these were uric acid stones. There may also be hypercalciuria, and a few patients have had exercise-induced acute kidney injury, thought to be due to acute tubular injury by passage of urate “gravel” in association with volume depletion and reduced urine pH. Most patients require no treatment, but if they are forming uric acid stones, they should maintain a high fluid intake. Urine alkalinization and allopurinol can be used for patients with persistent uric acid stones.

Familial Juvenile Hyperuricemic Nephropathy and Medullary Cystic Kidney Disease Type 2

Familial juvenile hyperuricemic nephropathy (FJHN) is a rare autosomal dominant condition characterized by hyperuricemia associated with a tubular defect in uric acid excretion.³⁸ Children develop progressive renal impairment with interstitial fibrosis and glomerulosclerosis. The hyperuricemia is due to renal underexcretion of uric acid. Diagnosis is suggested by a fractional excretion of uric acid of less than 5% (normal, 10% to 15%). Controversy exists as to whether lowering of serum uric acid slows the progression of renal failure; the studies reporting benefit have usually involved starting of a xanthine oxidase inhibitor early in the course of the disease. Isosthenuria and hypertension are common, and some patients have renal salt wasting. Many of the features of FJHN are also seen in medullary cystic kidney disease type 2 (MCKD2).³⁹ Most of these patients have a defect in the gene *UMOD*, located on chromosome 16p12,

coding for the Tamm-Horsfall/uromodulin protein. There is some evidence that this mutation may interfere with the function of the Na-K-2Cl transporter, leading to a secondary increase in proximal sodium and urate reabsorption. This mutation may also lead to deposition of abnormal protein in the endoplasmic reticulum and ultimately cell death.

Sickle Cell Disease

Jan C. ter Maaten, Fatiu A. Arogundade

DEFINITIONS

Sickle cell disease is an autosomal recessive inherited disorder, predominantly of the African race. The gene for sickle hemoglobin (hemoglobin S, or HbS) results in the replacement of the normal glutamine by valine in the sixth position of the β -globin subunit, thereby changing the configuration of the hemoglobin molecule and enhancing the aggregation of hemoglobin molecules during cellular or tissue hypoxia, dehydration, or oxidative stress. This aggregation decreases the pliability of the erythrocytes and may distort their shape to a characteristic crescent or sickle, resulting in their premature destruction (hemolysis) and frequent, widespread vaso-occlusive episodes with subsequent acute and chronic organ damage. Sickle cell anemia occurs in those homozygous for HbS or in heterozygotes when HbS coexists with another abnormal hemoglobin (e.g., hemoglobin C, β -thal chains). *Sickle cell trait* occurs in those heterozygous for HbS when the other hemoglobin molecule is normal.

Sickle cell nephropathy describes the structural and functional abnormalities of the kidney in sickle cell disease.

SICKLE CELL DISEASE

Epidemiology

Sickle cell disease was first recognized in West Africa. The high prevalence of HbS in this region probably represents a survival benefit because the presence of sickle cell trait protects against malaria. Nowadays, sickle cell disease is a worldwide health problem because HbS has spread throughout Africa, around the Mediterranean, and to the Middle East and India as well as to the Caribbean, North America, and northern Europe. The prevalence of the sickle cell gene is about 8% in African Americans and about 25% in adult Nigerians and in some areas in equatorial Africa, Saudi Arabia, and India.

Restriction enzyme techniques have identified several hemoglobin S haplotypes, mutations of the HbS molecule, that have probably arisen independently of each other. There are four major types in Africa—the Benin, Senegal, Cameroon, and Bantu (or Central African Republic)—and one Asian haplotype. Variations in these haplotypes determine disease severity; for example, the Senegalese haplotype is associated with a higher hemoglobin F (HbF) concentration and has a better prognosis than others. In a sample population of Nigerians, Benin haplotype was detected in 92.3%.¹ Gender influences disease severity; female HbSS subjects with Benin haplotype have a higher HbF level than male subjects do.

Pathogenesis

Genetics

Sickle cell disease comprises a group of heterogeneous disorders that share the presence of the gene for HbS, either homozygous (i.e., sickle cell anemia, HbSS) or double heterozygous (i.e., the combination of HbS with another abnormal hemoglobin).^{2,3} Sickle cell anemia is the most common form. The most common double heterozygous disorders are the combinations of hemoglobin S with hemoglobin C (HbSC) and β -thalassemia (HbS-thal). Subjects with HbS-thal may produce reduced amounts of normal β chains (HbS- β^+ -thal), but not always (HbS- β^0 -thal). Subjects with a sickle cell trait or carrier state are heterozygous for HbS only.

Pathophysiology

The characteristic pathophysiologic feature in sickle cell disease is the episodic vaso-occlusive crisis, which can be triggered by several factors, including infection, hypoxia, hypovolemia, hypothermia, acidosis, and hyperosmolality. The common denominator is the occurrence of inflammation or cellular stress. The two key processes in the pathophysiology of vaso-occlusion are adhesive interactions between the sickle erythrocytes and the endothelium and the subsequent polymerization of HbS.

Sickle Cell Adherence Sickle cells have enhanced adherence to the endothelium compared with normal erythrocytes. This is increased by endothelial cell activation, from inflammation-associated proinflammatory cytokines such as tumor necrosis factor- α , interleukin-1 β , and interferon- γ . Expression of leukocyte adhesion molecules on endothelial cells is induced, as is the release of procoagulant factors such as von Willebrand factor and thrombospondin (Fig. 49.1). The adhesion of sickle erythrocytes to the endothelium delays the capillary transit time, which allows polymerization of HbS and sickling to occur. Hypoxia distal to the occlusion further worsens the sickling process.

Polymerization of Hemoglobin S When HbS polymerizes, the hemoglobin molecules adhere to each other and aggregate into chain-like formations.⁴ Polymerization changes the shape of the red cell, increases its rigidity, and causes sickling (Fig. 49.2). Polymerization is dynamic and depends on three independent variables: the degree of cellular hypoxia, the intracellular hemoglobin concentration, and the presence or absence of hemoglobin F (fetal hemoglobin, HbF).⁴ Deoxygenation of HbS causes a change in the conformation of the β -globin subunits, which promotes the interaction of HbS molecules. The intracellular

hemoglobin concentration can increase through cellular dehydration caused by membrane transport lesions, especially activated potassium-chloride cotransport and calcium-activated potassium efflux. The net efflux of potassium chloride leads to a decrease in intracellular volume, which increases the rate of HbS polymerization. Novel therapies minimizing the passive transport of cations may reduce cellular dehydration and consequent polymerization in experimental animals.⁵ The presence of HbF decreases the polymerization tendency by reducing the concentration of HbS. Possible mechanisms of vaso-occlusion and ensuing vessel damage are shown in Figure 49.3.⁶

Clinical Manifestations

The clinical manifestations of sickle cell disease are individual and age dependent (Fig. 49.4). A chronic low-grade hemolytic anemia always occurs and predisposes to gallstones. The most prevalent clinical problem is periodic crises of bone pain. During the first years of life, it presents as the hand-foot syndrome, and in the course of life, it can result in avascular necrosis of the heads of the femur and humerus. Other disabling complications include stroke resulting from occlusion of major cerebral vessels, the acute chest syndrome, priapism, chronic leg ulceration, and chronic pulmonary disease with pulmonary hypertension.^{7,8}

Figure 49.1 Principal interactions responsible for the adhesion of a sickle erythrocyte to the microvascular endothelium. Thrombospondin acts as a bridging molecule by binding to CD36 on the surface of an endothelial cell and to CD36 or sulfated glycans (SO₄glyc) on a sickle reticulocyte. Vascular cell adhesion molecule 1 (VCAM-1) on endothelial cells can bind directly to the $\alpha_4\beta_1$ integrin on the sickle reticulocyte. (Modified with permission from reference 4.)

Patients with sickle cell disease are prone to infections because of functional asplenia early in life as a result of splenic sequestration, recurrent splenic infarction, and consequent autosplenectomy. Ordinary bacterial infections, especially with encapsulated organisms, can be fatal in these patients. Bacterial isolates during invasive bacterial infections show *Streptococcus pneumoniae* (38%), *Salmonella* species (33%), *Haemophilus influenzae* (14%), *Escherichia coli* (11%), and *Klebsiella* species (4%).⁹ *S. pneumoniae* and *H. influenzae* occur predominantly before 5 years of age, *Salmonella* increases almost linearly with age, and *Klebsiella* and *E. coli* predominate in patients older than 10 years. Pneumococcal infections carry high morbidity and mortality rates in the early years of life, necessitating vaccination or prophylaxis.²

Fever is common in patients with sickle cell disease. Common complications accompanying fever are painful crisis and acute chest syndrome. Bacteremia is not always confirmed, and in some cases, the fever may be viral in origin or related to infections due to atypical organisms. Nevertheless, early antibiotic treatment is recommended pending microbiologic information.

There are remarkable differences in clinical severity and outcome of disease. Sickle cell trait is a rather benign condition. Patients with HbSS tend to have more severe disease than do those with HbSC. Likewise, subjects with HbS- β^+ -thal do better than those with HbS- β^0 -thal. The Bantu haplotype is associated with the highest frequency of organ damage. However, the severity of disease may also differ among subjects with an identical genotype. In part, these differences can be explained by the amount of HbF present because it protects against clinical severity. In addition, endothelial factors probably play an important role. It has been shown that the degree of adherence between sickle erythrocytes and endothelial cells correlates with the clinical severity of disease. Also, a relation has been found between circulating activated endothelial cells of microvascular origin and the onset of painful sickle cell crises.¹⁰

Natural History

Life expectancy is reduced in sickle cell disease, especially in subjects with symptomatic disease. An increased risk for early death is associated with low levels of HbF, renal failure, the acute chest syndrome, and seizures.^{8,11} Childhood survival to age 20 years has improved during the past decades. In the course of life, irreversible organ damage due to arterial and capillary microcirculation obstructive vasculopathy gradually becomes more prevalent. The diagnosis of a clinically evident form of organ damage, such as leg ulcer, osteonecrosis, or retinopathy, predicts the development of a more lethal form of organ damage, such as

Figure 49.2 Sickle cells. **A**, Characteristic sickle cell erythrocytes in peripheral blood film of a patient with homozygous sickle cell anemia. **B**, Electron micrograph showing two normal and two sickle-shaped erythrocytes. (Courtesy Professor Sally C. Davies.)

Figure 49.3 Pathophysiologic mechanisms of damage to vessels in sickle cell disease. Inflammation activates the endothelium and stimulates the upregulation of adhesion molecules and adherence of sickle cells to the endothelium. This promotes the sickling of erythrocytes, increases the blood viscosity, and causes sludging in the microcirculation (eventually with microvascular thrombosis and infarction). After restoration of blood flow, vascular remodeling may contribute to persistent impairment of tissue blood flow. (Modified with permission from reference 6.)

chronic lung disease, renal failure, or stroke.¹² Overall, the primary causes of death in patients with sickle cell anemia are chronic lung disease in 20%, renal failure in 14%, and stroke in 10%. In younger patients, the primary cause of death is infection; in older patients, the primary cause of death is irreversible organ damage (Fig. 49.5).

Treatment

Management of sickle cell disease is primarily directed at the relief of symptoms and prevention of complications, whereas newer treatments are being devised that target the pathophysiologic changes of the disease.¹³ Daily oral penicillin for children 2 to 5 years of age is effective in reducing both the infection rate and the mortality related to pneumococcal infection.¹⁴ Immunization against pneumococcus is recommended for children at 2 years of age, with booster doses at 5 years of age, although protection from current vaccines is imperfect. Immunization against influenza in children is also important.

Empiric broad-spectrum antibiotics effective against gram-positive and gram-negative organisms should be used in adults with fever pending microbiologic confirmation. A commonly prescribed antibiotic is amoxicillin.

Sickle cell crises are managed with oxygen therapy, rehydration with intravenous fluids, red cell transfusions, and analgesia. In severe cases, exchange red cell transfusions may be effective. Hydroxyurea treatment in subjects with sickle cell anemia and

recurrent vaso-occlusive events decreases the incidence of painful crises and acute chest syndrome and overall mortality; butyrate compounds, deoxyazacytidine, and various combinations with erythropoietin are still being tried.^{13,15} Hematopoietic stem cell transplantation is a potentially curative treatment of sickle cell disease; it is associated with an 80% to 85% disease-free survival rate in several series.¹⁶ Young and presymptomatic patients with high-risk features of severe disease benefit the most from hematopoietic stem cell transplantation.

SICKLE CELL NEPHROPATHY

Pathogenesis

The hallmark of sickle cell nephropathy is the combination of impaired renal concentrating capacity and a normal diluting capacity.^{17,18}

Concentrating Capacity

The defect in concentrating capacity results from loss of the countercurrent exchange mechanism in the inner renal medulla through loss of the vasa recta and long loops of Henle of the juxtamedullary nephrons (Fig. 49.6). The vasa recta of the juxtamedullary nephrons present an ideal setting for sickling. The renal medulla is relatively hypoxic and hyperosmotic, the blood viscosity is increased in the medullary circulation, and medullary blood flow is slow. Studies in transgenic sickle cell

Figure 49.4 Age distribution of clinical problems in sickle cell disease. (Modified with permission from reference 2.)

mice have demonstrated distention and congestion of the vasa recta under hypoxic conditions. This environment facilitates the sickling of erythrocytes, formation of intravascular microthrombi, and obstruction of blood flow through the vasa recta. The loss of vasa recta has been confirmed by microradioangiographic studies (Fig. 49.7).¹⁹ Histologic examination of the medulla shows edema, focal scarring, and interstitial fibrosis resulting in tubular atrophy. Ischemic infarction in the vasa recta sometimes causes papillary necrosis. The concentration defect is found to be reversible in young children when sickling is prevented after multiple transfusions of normal blood, but it becomes irreversible thereafter. Adults with sickle cell anemia cannot concentrate the urine above 450 mOsm/kg H₂O. This relates to the interstitial osmolality at the transition of the outer and inner medulla, at the tips of the short loops of Henle of the cortical nephrons. Subjects with sickle cell trait or hybrid sickling disorders show intermediate concentrating defects. Maximal osmolality varies from 400 to 900 mOsm/kg H₂O in sickle cell trait and from 400 to 700 mOsm/kg H₂O in HbSC and declines further with aging.

Diluting Capacity

The diluting capacity is normal as a result of the intact reabsorptive function of the superficial loops of Henle of the cortical nephrons. These are supplied by peritubular capillaries, which present a less ideal setting for sickling than the vasa recta. In contrast to the diluting capacity, the free water reabsorption, or capacity to generate negative free water balance, is impaired by defective trapping of solute in the inner medulla.

Figure 49.5 Mortality in sickle cell disease. Causes of death among 232 HbSS patients, comparing patients younger than 20 years (46 died) with patients older than 20 years (186 died). The infection category includes both bacterial and viral diseases. (Modified with permission from reference 12.)

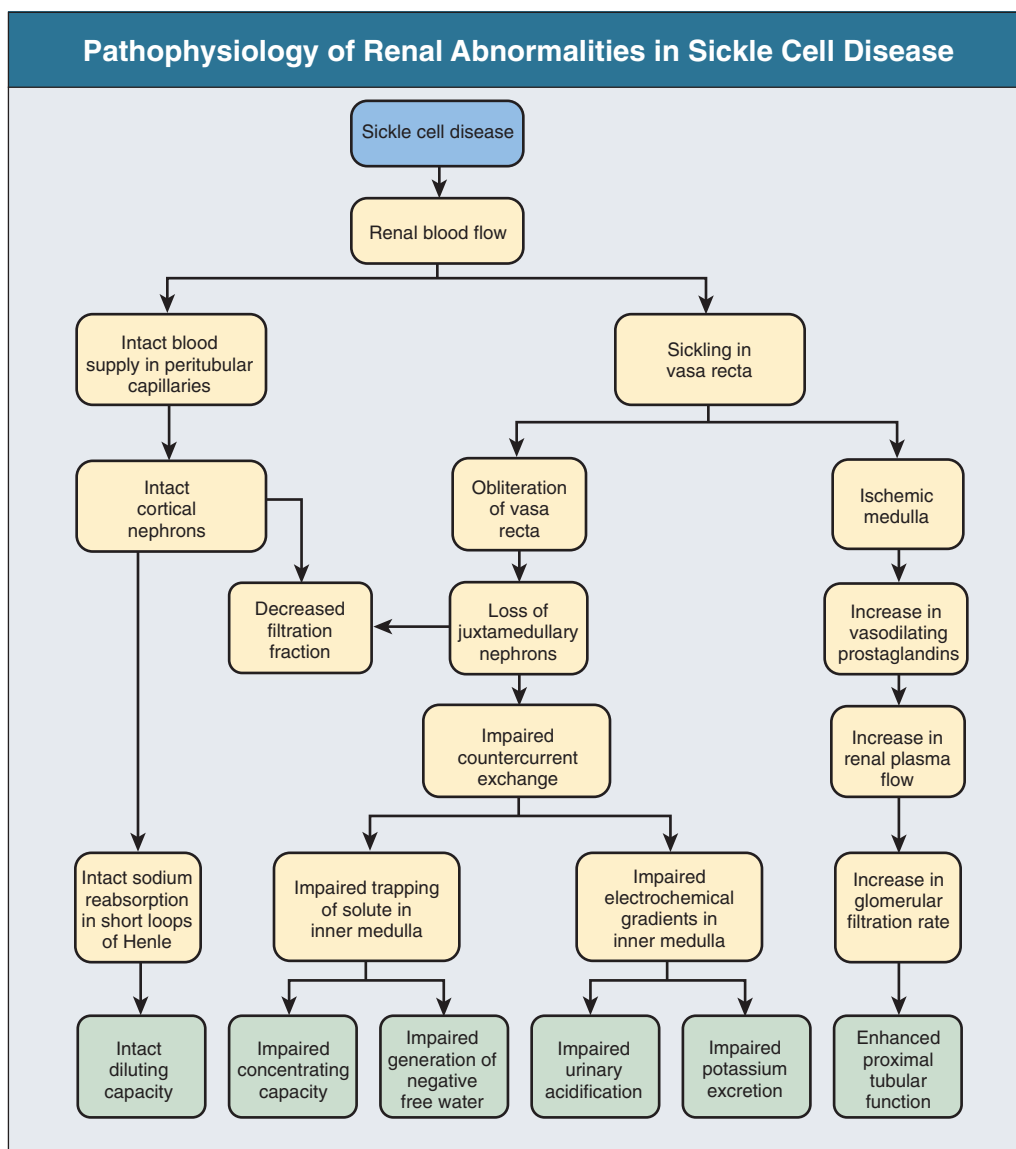

Figure 49.6 Pathophysiology of renal abnormalities in sickle cell disease.

Urine volumes are typically higher than normal, a consequence of impaired concentrating ability. Response to a water deprivation test in sickle cell disease is usually positive with marked elevation of endogenous antidiuretic hormone, and response to desmopressin is poor. Because isostenuria is typical, there is a susceptibility to normonatremic dehydration.

Other Tubular Abnormalities

Defects in urinary acidification and potassium excretion are other distal nephron function abnormalities.¹⁸ These may become overt only when there is an increased supply of acid and potassium, for example, during rhabdomyolysis. The exact causes of these defects are unknown, but they probably reflect failure to maintain the necessary energy-requiring hydrogen ion and electrochemical gradients along the collecting ducts due to the impaired medullary blood flow and hypoxia. The impaired potassium excretion is aldosterone independent.

In contrast to the functional abnormalities of the distal nephron, proximal tubular function is enhanced. Reabsorption of phosphate and β_2 -microglobulin and secretion of uric acid

and creatinine in the proximal tubule are increased. Therefore, creatinine clearance overestimates glomerular filtration rate (GFR) considerably. The cause of the enhanced proximal function is not clear, but it probably represents a secondary compensatory mechanism to correct for defects in medullary function.

Renal Hemodynamics

Renal hemodynamics show remarkable changes in the course of the disease (Fig. 49.8). Young subjects with sickle cell disease have increases in renal plasma flow (RPF) and renal blood flow and, to a lesser extent, in GFR. The increased RPF is ascribed to increased release of vasodilator prostaglandins as a result of medullary ischemia because prostaglandin inhibition significantly reduces RPF and GFR. Studies in transgenic sickle cell mice suggest that increased nitric oxide production from interaction between sickled erythrocytes and the endothelium also contributes to renal vasodilation. The decrease in filtration fraction may be caused by selective damage of juxtamedullary nephrons, which have the highest filtration fractions.

Figure 49.7 Microradioangiography showing loss of vasa recta in sickle cell nephropathy. **A**, Kidney from a control subject showing normal vasa recta. **B**, A patient with sickle cell anemia, with the absence of the vasa recta. (Modified with permission from reference 19.)

Figure 49.9 Focal segmental glomerulosclerosis in sickle cell nephropathy. Segmental sclerosis involving the upper half of the glomerulus. (Courtesy Professor J. Weening.)

Glomerular Injury

Glomerular hypertrophy is an early manifestation of sickle cell nephropathy. Histologic examination of the kidneys of young children shows glomerular enlargement and congestion, especially in the juxtamedullary glomeruli. Both afferent and efferent arterioles of these glomeruli may be dilated. In young adult patients with sickle cell anemia, there is a distinct pattern of glomerular dysfunction, with impaired glomerular permselectivity, increased ultrafiltration coefficient, glomerular hyperfiltration, and proteinuria.^{20,21} Prolonged glomerular hyperfiltration may cause further glomerular injury. This is supported by the common histologic finding of focal segmental glomerulosclerosis (FSGS) in adult patients with sickle cell disease (Fig. 49.9).²² Two patterns of FSGS have been described: a “collapsing” and an “expansive” pattern.²³ The initial collapsing pattern has been attributed to progressive obliteration of glomerular capillaries by red blood cell sickling in maximally hypertrophied glomeruli. The expansive pattern is characterized by an expansive sclerosis with increased mesangial matrix and further capillary obliteration; it is ascribed to sustained or increasing hyperfiltration.²³

Frequencies and Etiology of Renal Abnormalities Associated with Sickle Cell Disease				
Type of Renal Disease	Etiology	Sickle Cell Anemia	Sickle Cell Trait	HbSC and HbS-thal
Impaired concentrating capacity	Loss of vasa recta of juxtamedullary nephrons	Irreversible defects in all adults	Intermediate defects in all adults' nephrons	Intermediate defects in all adults
Impaired urinary acidification	Incomplete form of distal renal tubular acidosis	Almost all, during acid loading	Rare	At least 30%, during acid loading
Impaired potassium excretion	Aldosterone independent	Almost all, during potassium loading	Rare	Unknown; probably at least 30%
Hematuria	Infarction, extravasation of blood in renal medulla	Common	3%–4%	Common
Proteinuria	Glomerular hyperfiltration plus impaired permselectivity	Up to 50%–60% with increasing age	Rare	20%–25%
Nephrotic syndrome	FSGS most common	About 4%	Rare	0%–4%
Chronic renal failure	See Figure 49.8	4.2%–4.6%	Rare	About 2.4%
Renal medullary carcinoma	Possible genetic predisposition	Rare	Absolutely rare, relatively frequent	Rare

Figure 49.10 Frequencies and etiology of renal abnormalities associated with sickle cell disease.

In older subjects, progressive ischemia and fibrosis with obliteration of glomeruli can be found. Glomerular function studies show a decrease in glomerular basement membrane pore number and a size selectivity defect in subjects with renal impairment.²⁴ Ultimately, a combined decrease in ultrafiltration capacity and RPF can result in end-stage renal disease (ESRD).²⁰

Hormones in Sickle Cell Nephropathy

There is relative erythropoietin (EPO) deficiency in sickle cell disease; that is, EPO levels do not increase to the expected level for the degree of anemia, perhaps because of the right-shifted hemoglobin-oxygen dissociation curve. In addition, EPO levels fall with the decline in renal function, probably as a result of renal damage due to the sickling process.

Elevated serum renin and aldosterone have been reported in some studies, under standard and volume-depleted conditions, although in general normal values are found in sickle cell anemia.¹⁷

Hormone infusion studies have helped to localize sites of action in the kidney. Failure of low-dose infusion of atrial natriuretic peptide (ANP) to increase natriuresis in sickle cell anemia²⁵ suggests that ANP at this dosage exerts its natriuretic effect in the long loops of Henle of the juxtamedullary nephrons, whereas insulin induces a similar sodium retention in patients with sickle cell anemia and normal subjects,²⁵ suggesting that its antinatriuretic effect is probably localized at a distal tubular site other than the long loops of Henle. Urinary endothelin 1 is elevated in asymptomatic sickle cell disease patients. It correlates with a urine concentrating defect and microalbuminuria.²⁶

CLINICAL MANIFESTATIONS OF SICKLE CELL NEPHROPATHY

The presentation of the clinical manifestations of sickle cell nephropathy shows an age-dependent pattern. The frequency and etiology of the renal abnormalities associated with sickle cell

anemia, sickle cell trait, and the most common double heterozygous disorders (HbSC and HbS-thal) are listed in Figure 49.10.

Hematuria

Hematuria is a common clinical manifestation in sickle cell anemia and the hybrid sickling disorders and occurs in 3% to 4% of subjects with sickle cell trait at some time. There is often persistent microscopic hematuria with episodic gross hematuria. The hematuria may follow relatively minor trauma. Hematuria occurs more often in males and is usually unilateral, originating from the left kidney in 80% of patients. Urinary erythrocytes are typically isomorphic, but sickled erythrocytes are occasionally found in the urine.

Pathogenesis

Sickling The main mechanism of hematuria probably relates to the sickling of erythrocytes in the vasa recta and microthrombotic infarction and extravasation of blood in the renal medulla. Histologic examination typically shows severe stasis in peritubular capillaries of the cortex and, especially, the medulla and extravasation of blood into the collecting system.

Papillary Necrosis Papillary necrosis is a frequent cause of hematuria in sickle cell anemia, hybrid sickling disorders, and sickle cell trait (Fig. 49.11). The incidence of papillary necrosis varies from 23% to 67% in studies of selected patients with sickle cell disease.^{18,27} This complication results from obliteration of the vasa recta, with medullary necrosis and fibrosis. The large analgesic consumption by these patients because of their bone pain may also contribute to papillary necrosis. The most common presenting symptom is painless macroscopic hematuria. Other presentations are renal colic caused by the passage of blood clots or necrotic papillae, microscopic hematuria, symptoms of urinary tract infection, and, rarely, acute renal failure. Papillary necrosis may also be asymptomatic and is frequently an incidental finding during imaging.

Figure 49.11 Papillary necrosis in sickle cell disease. Intravenous urography shows abnormal calyces with filling defects (arrows).

Nutcracker Phenomenon The left-sided predominance of hematuria has been attributed to the so-called nutcracker phenomenon, compression of the left renal vein between the aorta and the superior mesenteric artery, thereby increasing the pressure in the renal vein. This may especially contribute to the development of hematuria in sickle cell patients because the increased renal vein pressure could worsen anoxia in the renal medulla, thereby increasing the likelihood of sickling in the left kidney.

Clinical Manifestations

Painless macroscopic hematuria often presents after physical activity or minor renal trauma or is associated with hypoxic challenges, for example, airplane flights. It usually is accompanied by a substantial fall in hematocrit. Bleeding typically remits spontaneously within a few days.

Diagnosis and Differential Diagnosis

Urinalysis can exclude the presence of myoglobinuria and rhabdomyolysis, which can mimic hematuria. Rhabdomyolysis can be provoked during strenuous exercise and dehydration and may also occur during severe sickle cell crises. The coexistence of hematuria with leukocyturia is not unusual and does not necessarily indicate a urinary tract infection, even in combination with flank pain. Infection must be confirmed by examination of the urinary sediment and urine cultures.

Sickle cell trait has been reported in 50% of African Americans with ESRD caused by autosomal dominant polycystic kidney disease (ADPKD) but in only 7.5% of African American patients with other causes of ESRD. In addition, patients with ADPKD and sickle cell trait had an earlier onset of ESRD.²⁸ The prevalence of sickle cell disease in ADPKD has not been reported.

Recently, renal medullary carcinoma has been recognized as a specific entity in sickle cell nephropathy.^{18,29} It is an aggressive form of renal cell carcinoma that appears uniquely to affect patients with sickle cell hemoglobinopathies, particularly sickle cell trait or HbSC, especially in teenagers and young adults. Chronic medullary hypoxia is thought to contribute to its pathogenesis.⁹ The tumors are resistant to chemotherapy and tend to be metastatic at the time of diagnosis, with a reported mean survival from the time of surgery of only 15 weeks. It is not yet clear whether regular screening for renal medullary carcinoma in young patients with sickle cell disease or trait could result in an early diagnosis and a better survival.²⁹ Gross hematuria, flank pain, and weight loss are ominous signs of malignancy, particularly in young patients with sickle cell trait. The tumor is typically located deep in the parenchyma, unlike Wilms' tumor or renal cell carcinoma. Immunohistochemical analysis for

epithelial cell markers (e.g., CAM 5.5), epithelial membrane antigen, and cytokeratin may assist in diagnosis.

von Willebrand disease has occasionally been described in subjects with sickle cell trait and gross hematuria.

Further evaluation is indicated for patients with severe or prolonged hematuria that is resistant to conservative therapeutic measures. Ultrasound examination will be normal unless there is papillary necrosis or a coincidental cause of hematuria, such as polycystic kidney disease, renal calculus, or tumor. Intravenous urography used to be the method of choice for diagnosis of papillary necrosis, but it does not distinguish reliably between papillary necrosis and other causes of filling defects in the pyelogram, including blood clots, neoplasm, calculus, and hemangioma. Ultrasound is therefore preferred, although it is suggested that contrast-enhanced computed tomography may better depict a full range of typical features.³⁰ The role of magnetic resonance imaging in this setting has not yet been sufficiently evaluated.

Cystoscopy is not routinely required but is indicated if the episode of hematuria is atypical, for example, a first episode of macroscopic hematuria in a patient older than 40 years or an episode that persists for more than 2 weeks. Cystoscopy may also be required to lateralize the source of the bleeding if surgical intervention is considered (see later).

Renal angiography only rarely identifies the bleeding source, but when it does so, it can be followed by embolization. However, the optimal approach in any institution depends on local experience with specific techniques.

Treatment

The therapeutic strategy for hematuria depends on the severity and duration of a specific bleeding episode. Bleeding will stop in most patients spontaneously or after a period of bed rest, although it may occasionally last for weeks or months. About half of patients will have recurrent episodes.

Initial therapeutic measures include bed rest and interventions aimed at retardation of the sickling process in the anoxic renal medulla. A high urine flow rate should be induced by intravenous fluid administration and diuretics to further reduce medullary tonicity and the urine alkalinized by administration of sodium bicarbonate by mouth or by vein, with a target urine pH of 8. Blood transfusion with normal HbA is indicated if anemia becomes severe; this may also decrease the sickling process. If necessary, bladder irrigation is performed for removal of blood clots.

Hyperbaric oxygen therapy may be helpful but has not been formally evaluated. Irrigation of the pelvicalyceal system with silver nitrate has also been described. The antifibrinolytic agent ϵ -aminocaproic acid, although effective, may be associated with adverse renal outcomes and is not recommended.

Unilateral nephrectomy has occasionally been necessary in patients with persistent, life-threatening hematuria refractory to conservative approaches. Full evaluation for another cause of hematuria, including cystoscopy to exclude a bladder lesion and to establish which kidney is the source of bleeding, is required before proceeding with nephrectomy.

Urinary Tract Infection

Subjects with sickle cell disease have an increased susceptibility to bacterial infections; even low-grade bacteremia with a common organism may be fatal. In addition to the impaired immunity that is a consequence of autosplenectomy, there is opsonic antibody deficiency, which predisposes to bacterial infections. The precise incidence of urinary tract infections is not well defined. However,

the incidence of asymptomatic bacteriuria during pregnancy and the puerperium appears to be twice as high in women with sickle cell disease or trait as in women without sickle cell disease and requires appropriate therapy (see Chapter 42).

Pyelonephritis and urosepsis, like any other infection, may precipitate a sickle cell crisis. One should especially be aware of this possibility in young children, who often do not complain of urinary tract symptoms. Most common organisms isolated include *E. coli*, *Klebsiella* species, and other gram-negative Enterobacteriaceae. Invasive bacterial infections with *E. coli* occur especially in females after the age of 15 years, suggesting a greater chance of urinary tract infections in relation to sexual activity.

Acute Kidney Injury

People with sickle cell disease sometimes present with features of acute kidney injury (AKI). AKI, defined as a doubling of serum creatinine, is reported in 10% of hospitalized patients with sickle cell anemia.³¹ A potentially reversible renal dysfunction with significant reduction in GFR could occur during vaso-occlusive crises.³²

Etiology

A prerenal cause of AKI will be found in more than half of patients, especially volume depletion in the setting of sickle cell crisis. Patients with sickle cell disease are prone to AKI caused by volume depletion because of impaired urine concentrating capacity; it is therefore typically nonoliguric. A less frequent prerenal cause is congestive heart failure.

Typical intrinsic renal causes of AKI are rhabdomyolysis, sepsis, and drug nephrotoxicity. Less common are renal vein thrombosis and hepatorenal syndrome (caused by hemosiderosis-induced hepatic failure). Both exertional and nontraumatic rhabdomyolysis have been reported in patients with sickle cell disease; the latter especially occurs during a sickle cell crisis and has been ascribed to intravascular sickling and muscle ischemia. Rhabdomyolysis is a common finding in patients who develop multiorgan failure during severe sickle cell crises, in addition to the acute chest syndrome, which further contributes to AKI. The most typical postrenal cause of AKI is urinary tract obstruction by necrotic papillae or blood clots.

Treatment

Treatment and recovery of renal function depend on the specific underlying pathologic process. Metabolic acidosis may be prominent and should be actively corrected with sodium bicarbonate. Patients with volume depletion have a favorable outcome after fluid replacement.³¹ Renal function may recover in patients with sepsis and rhabdomyolysis, although temporary renal replacement therapy may be necessary. AKI as a part of multiorgan failure during a severe sickle cell crisis may show a dramatic improvement with aggressive red cell transfusion therapy, although some renal function loss may persist.

Proteinuria and Nephrotic Syndrome

Microalbuminuria has been reported in 19% to 26% of children with sickle cell anemia.^{33,34} The presence of microalbuminuria is directly related to age and inversely related to hemoglobin levels. Proteinuria has been reported in 17% to 33% of subjects with sickle cell disease by semiquantitative or dipstick measurement.⁸ The prevalence of proteinuria is lower in subjects with coinheritance of sickle cell anemia and α -thalassemia than in those with

sickle cell anemia and intact α -globin genes (13% versus 40%).³⁵ The “renoprotective” effect of α -globin gene microdeletions could be related to a lower mean corpuscular volume or lower erythrocyte hemoglobin concentration in sickle erythrocytes. The frequency of proteinuria increases with age (56% in subjects ≥ 40 years), and its presence is associated with renal impairment.

The nephrotic syndrome has been estimated to occur in 4% of patients with sickle cell anemia. The eventual development of renal failure appears virtually inevitable once the patient has nephrotic syndrome.

Pathology

The most common pathologic lesion is FSGS,^{22,23} which is also the major lesion in patients who develop renal failure. Another specific pathologic lesion is a form of membranoproliferative glomerulonephritis (MPGN) with mesangial expansion and basement membrane duplication.³ The general absence of immune complexes and electron-dense deposits discriminates this entity from idiopathic MPGN type I. It has been proposed that this form of MPGN is caused by intracapillary red cell fragmentation. Fragments of erythrocytes become lodged in isolated capillary loops and are continuously phagocytosed by mesangial cells. As a result, the mesangium expands and lays down new basement membrane material.

Patients may become hepatitis C positive from multiple blood transfusions, which may also be associated with MPGN, although it is rare with appropriate screening procedures before transfusion. In our series, hepatitis C positivity was observed in only 1 patient (0.26%), a reflection of the generally low seroprevalence rate in the environment.⁸ On occasion, other causes have been reported, such as poststreptococcal glomerulonephritis, minimal change disease, and immune complex-mediated glomerulonephritis. Glomerulonephritis has also been described in association with aplastic crises in parvovirus infection. Renal vein thrombosis should be considered when nephrotic syndrome develops in sickle cell disease, but its incidence is not exactly known.

Treatment

Theoretically, dietary protein restriction may reduce hyperfiltration and retard the development of renal failure in those with FSGS, but this has not been evaluated specifically in sickle cell disease.

Short-term treatment with angiotensin-converting enzyme (ACE) inhibitors significantly reduces the degree of proteinuria without affecting blood pressure or renal hemodynamics. More prolonged ACE inhibition reduces proteinuria with a slight decrease in blood pressure. However, it remains to be established whether long-term treatment with ACE inhibitors or angiotensin receptor blockers (ARBs) delays the development of progressive renal failure. Combinations of ACE inhibitor and hydroxyurea have been found to be useful in retarding progression of microalbuminuria to overt proteinuria.^{33,34,36}

Prevention of hyperfiltration can, theoretically, also be obtained with nonsteroidal anti-inflammatory drugs (NSAIDs), but these drugs reduce RPF and GFR in sickle cell anemia and are thus contraindicated.

Sodium and Acid-Base Disturbances

Distal Tubular Function

Impaired potassium excretion and impaired urinary acidification are caused by an incomplete form of distal tubular acidosis.

However, hyperkalemia and metabolic acidosis are not present under normal circumstances and may become manifested only during potassium or acid loading, with mild renal impairment or volume depletion, and during rhabdomyolysis.^{17,18} Hyperkalemia may also develop more readily during treatment with NSAIDs, ACE inhibitors, β -blockers, potassium-sparing diuretics, or heparin.

Urine pH does not fall below 5 during acid loading tests unless maximal acidifying stimuli are used. The titratable acid and hydrogen ion excretion is reduced, whereas the ammonium excretion is either normal or decreased. Metabolic acidosis that develops during renal impairment or intercurrent diseases in sickle cell disease requires active treatment with sodium bicarbonate because acidosis stimulates the sickling process. Plasma bicarbonate should be monitored routinely and oral sodium bicarbonate supplements given to keep it within the reference range.

Proximal Tubular Function

Proximal tubular function abnormalities modify solute handling, producing increased reabsorption of phosphate and increased secretion of uric acid. Hyperphosphatemia may develop easily when renal function declines, necessitating dietary phosphate restriction and the use of phosphate binders early in renal impairment. The increased uric acid secretion protects patients with sickle cell disease against hyperuricemia, with elevated uric acid production resulting from hemolysis. However, the incidence of hyperuricemia and risk for gout increase with age as renal function declines.

Hypertension

Epidemiology

The prevalence of hypertension in patients with sickle cell anemia is about 2% to 6%, which is significantly lower than in age- and sex-matched control subjects.^{8,17,37} However, blood pressure in patients with sickle cell anemia is higher than in matched subjects with β -thalassemia and similar degrees of anemia. Hypertension in sickle cell anemia especially occurs in the presence of advanced renal failure.

Pathogenesis

It is not yet clear whether the relative hypotension compared with control subjects relates to the pathologic renal medullary condition in sickle cell disease or to other mechanisms. The kidney in sickle cell disease has a normal overall capacity for sodium conservation, despite a tendency to lose sodium and water through the medullary defect.^{17,37} This sodium conservation in sickle cell disease may follow stimulation of the renin-angiotensin system, which has been described in some but not all studies. The relative hypotension may be related to general vasodilation because skeletal vascular resistance is reduced in sickle cell patients. Increased production of vasodilatory prostaglandins or nitric oxide may be involved. Systemic vasodilation and increased flow is a compensatory mechanism for microcirculatory flow disturbances and intermittent microvascular occlusion.³⁸ Finally, reduced vascular reactivity has been demonstrated in sickle cell patients and may protect against blood pressure elevation.³⁷

Treatment

The antihypertensive treatment of choice is an ACE inhibitor or ARB because of the potential beneficial effects on the progression of proteinuria and renal failure and because of the reported

increments in plasma renin activity. However, the risk for hyperkalemia is increased. There are no specific recommendations on target blood pressure in sickle cell disease, and the targets for other nondiabetic nephropathies are appropriate.

An alternative therapeutic option is a calcium channel blocker, but those recognized to worsen proteinuria, like the short-acting dihydropyridines, should be avoided. Loop diuretics are less effective in patients with sickle cell disease because of the specific medullary defect.

Chronic Kidney Disease

Epidemiology

In a prospective, 25-year longitudinal study, chronic kidney disease (CKD) developed in 4.2% of 725 patients with sickle cell anemia and in 2.4% of 209 patients with HbSC.³⁹ The patients with sickle cell anemia were much younger at the time of the diagnosis of renal failure than those with HbSC (median age, 23.1 and 49.9 years, respectively). However, in another study of 368 patients with sickle cell anemia with an overall prevalence of CKD of 4.6%, the prevalence of CKD clearly increased with age.⁴⁰ The prevalence of CKD will probably increase even more in the future with further improved medical care and longer life expectancy. In our series, younger age at diagnosis and higher duration of sickle cell disease were found to strongly predict the development of nephropathy.⁸

Predictors of CKD are hypertension, proteinuria, hematuria, increasingly severe anemia, the nephrotic syndrome, and inheritance of the Bantu or Central African Republic β -globin gene cluster haplotype.³⁹ Apart from an apparent genetic predisposition, glomerular capillary hypertension and prolonged glomerular hyperfiltration seem to be important in the development of renal failure.

Natural History

Patients with sickle cell anemia and CKD have an increased mortality rate compared with patients without renal failure (Fig. 49.12). Patients with renal failure are also prone to

Figure 49.12 Survival in sickle cell anemia in the presence and absence of renal failure. (Modified with permission from reference 40.)

other manifestations of sickle-induced vasculopathy, such as cerebrovascular diseases, chronic restrictive lung disease, and leg ulcers, leading to frequent hospitalizations.³⁹ In the United States Renal Data System, patients with sickle cell nephropathy and ESRD had an increased mortality risk (hazard ratio, 1.52; 95% confidence interval, 1.27-1.82) compared with other patients with ESRD. However, patients with sickle cell nephropathy were less likely to receive renal transplantation, and the increased mortality risk did not persist after adjustment for transplantation.⁴¹ As nephropathy progresses in sickle cell disease, strategies aimed at retarding progression and preparations for eventual renal replacement therapy should be initiated. The changing profile of renal dysfunction in sickle cell disease with age and available treatment options are summarized in Figure 49.13.¹⁸

Treatment

To delay the development of progressive renal failure, it is important to control hypertension and to avoid the use of nephrotoxic drugs, especially NSAIDs. Although plausible, it remains to be established whether the reduction of the degree of proteinuria with either ACE inhibitors or a low-protein diet retards the progression of renal failure.

The response to EPO therapy is poor, even when high doses are used during long treatment periods. EPO treatment predominantly results in the release of HbS-containing reticulocytes, with only a modest increase in the more stable HbF. A marked increase in hemoglobin levels, although unexpected, may precipitate sickle cell crisis. Routine use of EPO is therefore not recommended, but it can be tried on an individual basis with higher doses than needed in other forms of ESRD. As an

alternative, supportive red cell transfusion may be necessary. Excessive iron accumulation should be prevented in patients undergoing regular transfusions, who are at risk for hemochromatosis, although organ dysfunction caused by tissue iron overload seems less predictable in sickle cell disease than in thalassemia major. Metabolic acidosis is also prominent and requires correction with sodium bicarbonate supplements.

ESRD in sickle cell disease has been treated successfully with hemodialysis, peritoneal dialysis, and transplantation. Hemodialysis has been used more frequently than peritoneal dialysis. Sickle cell crises are not common despite the potential for hypotension, hypoxemia, and cytokine release during hemodialysis. The 30-month survival rate of a group of 77 patients who were predominantly treated with hemodialysis was 59%, comparable to survival rates in other groups of patients with multisystem disorders receiving dialysis.

TRANSPLANTATION

Transplantation is an appropriate form of renal replacement therapy in sickle cell nephropathy. After kidney transplantation, 1- and 3-year patient survival rates are 90% and 75%, respectively; 1- and 3-year graft survival rates are 82% and 54%, respectively.⁴² These outcomes compare unfavorably with kidney transplantation for most other groups of patients. The adjusted mortality risk in sickle cell patients undergoing transplantation is higher at 1 year (relative risk, 2.95) and at 3 years (relative risk, 2.82).³⁵ Nevertheless, there is a trend toward improved survival in transplant recipients compared with dialysis-treated patients with sickle cell disease on the transplant waiting list.⁴³

In sickle cell disease, perioperative risks such as severe crisis and massive sickling can be reduced by preoperative transfusions of normal blood, thereby reducing the proportion of HbS. After transplantation, hematocrit increases and may even be higher than in patients with sickle cell disease and normal renal function. Sickle cell crisis may occur after transplantation, but it is not yet clear whether the increase in hematocrit enhances the risk for a crisis. Standard immunosuppressive therapy does not increase the risk for sickle cell crisis. However, caution is warranted with the use of antilymphocyte antibodies because the onset of a crisis has been related to this therapy in a few patients, perhaps as a consequence of increased cytokine release. The recurrence of hyposthenuria and sickle cell nephropathy after transplantation has occasionally been described.

Congenital Anomalies of the Kidney and Urinary Tract

John O. Connolly, Guy H. Neild

This chapter discusses congenital anomalies of the kidney and urinary tract that can result in renal problems and renal failure. Nearly half of the children who develop end-stage renal disease (ESRD) have asymmetric, irregularly shaped kidneys.^{1,2} This appearance, often referred to as bilateral renal scarring, is frequently associated with lower urinary tract anomalies including vesicoureteral reflux (VUR). The most serious conditions involve bladder outflow obstruction, and many can now be detected antenatally.

These cases were previously described as reflux nephropathy or chronic pyelonephritis; but with advances in genetics and developmental biology, it is becoming clear that many are due to primary renal malformations (renal dysplasia) often associated with congenital malformations of the ureter, bladder, and urethra. This is a change from the view that renal scarring and damage are secondary to the outflow problem and ureteral reflux. Although it is still a matter of some debate, the concept of acquired renal scarring is often wrong, and the British Association for Paediatric Nephrology now suggests that clinical distinction between reflux nephropathy and renal dysplasia is unnecessary.¹

CLINICAL PRINCIPLES

Congenital renal tract abnormalities may present in one of five settings:

1. Antenatal diagnosis by fetal ultrasound screening.
2. Failure to thrive in an infant or young child.
3. Investigation of urinary tract infection (UTI).
4. An incidental finding in a child or adult.
5. An adult with abnormal urinalysis, stones, hypertension, or renal impairment.

The identification of these problems always poses the following questions:

- What is the cause?
- What is the natural history?
- Is surgical intervention required?

Such patients fall into two broad groups. First, there is a group of patients who appear to have normal bladders without outflow obstruction and normal-caliber ureters when not mic-turating, described as having either primary VUR or primary renal dysplasia. Second, there is a group with some form of bladder outflow dysfunction that causes secondary VUR and dilated upper urinary tracts, the most common cause of which is posterior urethral valves in males.

As predicted by the Brenner hypothesis,³ small asymmetric kidneys with reduced glomerular filtration rate (GFR) develop all the features of glomerular hyperfiltration, with the onset of

progressive renal failure signaled by increasing proteinuria. This can now be significantly modified by treatment with renin-angiotensin blockade.⁴ The details of antenatal and pediatric management of these patients are beyond the scope of this chapter, which focuses on management in adolescence and adult life.

DEVELOPMENT OF THE URINARY TRACT

The urinary tract develops from the cloaca and intermediate mesoderm in parallel with the early differentiation of the metanephric blastema (future kidney) (Fig. 50.1).⁵⁻⁷ At the fifth week of fetal life, the mesonephric (wolffian) duct connects to the allantois and the cloaca. By the sixth week, the urorectal fold appears and divides this cavity, which separates the urinary system (urogenital sinus) from the rectum. Growth of the anterior abdominal wall between the allantois and the urogenital membrane is accompanied by an increase in size and capacity of this bladder precursor. The allantois remains attached to the apex of the fetal bladder and extends into the umbilical root, although it loses its patency and persists as the urachal remnant, the median umbilical ligament, which connects the bladder to the umbilicus. By the seventh week, there is a separate opening of the mesonephric duct into the bladder at what will become the vesicoureteral opening and the area known as the trigone. The distal part of the primitive urogenital sinus will form the definitive urogenital sinus. In females, this gives rise to the entire urethra and the vestibule of the vagina. In males, it gives rise to the posterior urethra, whereas the anterior urethra is formed from the closure of the urethral folds.

In the 6-week embryo, the mesonephric and paramesonephric (müllerian) ducts run in parallel. By 7 weeks, in the male, the müllerian duct starts to regress, and the wolffian duct will eventually develop into the epididymis and the caudal part of the vas deferens. In the female, the müllerian ducts fuse to become the uterovaginal cord, which opens into the urogenital sinus and will develop into the vagina.

As the urogenital tract develops, there is simultaneous development of the fetal kidney (see Fig. 50.1). In the absence of the ureteral bud, the metanephric kidney does not form. Fetal urine makes a significant contribution to the amniotic fluid by 16 weeks.

Pathogenesis of Maldevelopment

Renal development is orchestrated by the expression of transcription factors, growth and survival factors, and adhesion molecules.^{6,8,9} Mutations of genes encoding all classes of these

Figure 50.1 Development of the urinary tract. Growth and development of the ureter, pelvis, and calyces are shown in **A** to **D**. **A**, The metanephric kidneys first become detectable as small areas in the mesoderm close to the aorta. The primitive epithelial ureter buds off from the mesonephric duct and makes contact with the metanephric mesenchyme. **B**, Under the influence of signals from the ureter, the mesenchyme condenses and proliferates around the ureteral tip while there is simultaneous elongation and branching of the ureteral tip. **C** and **D**, A primitive pelvis appears, which then branches to form the divisions of the calyces. The branching process continues, with the epithelial system eventually differentiating into the nephrons of the renal parenchyma. As the fetus grows, there is ascent of the kidney due to the continuous rostral growth. **E**, Growth and development of the cloaca during weeks 5 to 6. **F**, Growth and development of the urogenital sinus into bladder and outflow tract during weeks 8 to 9.

molecules cause urinary tract malformations in mice.⁸⁻¹⁰ One family of transcription factor proteins contains the paired DNA-binding domain and is encoded by the PAX genes. Studies in mice show that these PAX genes regulate the development of brain, eyes, lymphoid system, musculature, neural crest, and vertebrae.^{11,12} PAX2 is expressed in the metanephros and in cell lineages that are forming nephrons and also in those that are destined to differentiate into the ureter, renal pelvis, and branching collecting duct system. The ablation of a single PAX2 allele in knockout mice causes impaired metanephric growth and fewer nephrons than normal as well as megaureter, a finding consistent with gross VUR.¹² WT1, which is mutated in a proportion of Wilms' tumors, is another transcription factor whose mutation is associated with abnormal urinary tract development.

Normal development appears to depend on urine flow from the fetal kidney. This requires peristalsis and no anatomic obstruction to flow. A number of diverse defects can now be unified as it becomes clear they play some key role in peristalsis. This may be due to defects in smooth muscle development or innervations in the ureter. For example, mice lacking the transcription factor "teashirt 3" fail to develop normal smooth muscle in the ureter and have congenital hydronephrosis without anatomic obstruction.¹³ Angiotensin plays a key role in initiating the peristalsis, and mice in whom the angiotensin type 1 receptor is knocked out fail to develop a renal pelvis and die of renal failure.⁹

Angiotensin type 2 receptor gene null mutant mice display congenital anomalies of the kidney and urinary tract. These include unilateral agenesis, unilateral megaureter and hydronephrosis, and pelviureteral junction (PUJ) obstruction and mimic

a range of abnormalities found in humans.⁹ Administration of angiotensin-converting enzyme (ACE) inhibitors throughout pregnancy in humans can cause hypotension and anuria in the baby with histologic features of renal tubular dysplasia. This phenotype is also caused by mutations in genes encoding renin, angiotensinogen, ACE, and angiotensin II receptor type 1.

Other syndromes associated with dysplasia and agenesis in which the mutation is now known include branchio-oto-renal syndrome (EYA1 mutation, transcription factor-like protein), Fraser syndrome (FRAS1 mutation, putative cell adhesion molecule), Kallmann syndrome (X-linked form, KAL1 mutation, cell adhesion molecule; autosomal form, FGFR1 mutation, growth factor receptor), and renal cysts and diabetes syndrome (HNF1 mutation, transcription factor).¹⁴

RENAL MALFORMATIONS

Congenitally abnormal kidneys may be large or small, cystic or irregular in outline, and absent or misplaced.

These conditions have traditionally been discussed on the basis of findings on intravenous urography (IVU), but the findings on computed tomography (CT) and magnetic resonance imaging (MRI) are now increasingly being emphasized.

Large Kidneys

Enlarged kidneys resulting from congenital problems are usually hydronephrotic or cystic. Wilms' tumor must also be considered. The differential diagnosis in adults of enlarged kidneys, both congenital and acquired, is shown in Chapter 5, Figure 5.4, and

Definitions of Renal Dysplasia and Malformation	
Term	Characteristics
Renal agenesis	Absence of the kidney or an identifiable metanephric structure
Renal aplasia	Severe dysplasia with an extremely small kidney, sometimes identifiable only by histologic examination
Renal dysplasia	Abnormal differentiation of the renal parenchyma with the development of abnormal structures, including primitive ducts surrounded by collars of connective tissue, metaplastic cartilage, a variety of nonspecific malformations such as preglomeruli of the fetal type, and reduced branching of the collecting ducts with cystic dilations and primitive tubules
Renal hypoplasia	Significantly reduced renal mass and nephron number without evidence of maldevelopment of the parenchyma
Renal multicystic dysplasia	Severe cystic dysplasia with extremely enlarged kidney full of cystic structures. It occurs as an isolated renal lesion in response to ureteral atresia and urethral obstruction. Ten percent of patients have a family history.

Figure 50.2 Definitions of renal dysplasia and malformation.

the differential diagnosis of cystic kidney disease is discussed further in Chapters 44 and 45.

Irregular Kidneys

Irregularity of the renal outline may result from fetal lobulation or a “dromedary hump,” neither of which has any functional implications. Much more important is the diagnosis of renal dysplasia.

Renal Dysplasia

The range of dysplastic and other malformations of the kidney is presented in Figure 50.2. It is clear that abnormalities of the ureter, bladder, and urethra are often associated with renal dysplasia.^{15,16} All types of renal dysplasia can also occur as isolated developmental anomalies. Renal dysplasia, although typically producing small, irregular kidneys, may sometimes be cystic or multicystic renal dysplasia.

Renal Hypoplasia (Oligomeganephronia)

Hypoplasia is defined as a congenitally small kidney (two standard deviations below the expected mean) that lacks evidence of parenchymal maldifferentiation (renal dysplasia) or of acquired disease sufficient to explain the reduced size. The term is often used loosely, however, and most patients with a small kidney and other malformations will have oligomeganephronia. This is a type of renal hypoplasia resulting from a congenital reduction in the number of nephrons. It results from arrested development of the metanephric blastema at 14 to 20 weeks of gestation with subsequent hypertrophy of glomeruli and tubules in the kidney. The hypertrophy and hyperfiltration result later in life in progressive nephron injury and sclerosis. Oligomeganephronia is recognized on renal biopsy by the large size of the glomeruli and tubules and the small number of glomeruli seen in a good core of renal cortex. It is reported in congenital syndromes caused by mutations in *PAX2* and hepatocyte nuclear factor 1 β .

Figure 50.3 Renal dysplasia. **A**, Gross bilateral scarring in a 20-year-old woman who has been assessed since the age of 2 years. Progressive scarring has been observed in the absence of urinary tract infections and obstruction. This probably represents primary renal dysplasia. **B**, CT IVU showing gross scarring of right kidney. (Courtesy Dr. A. Kirkham, University College Hospitals, London, UK.)

Differential Diagnosis of Scarred Kidneys

Dysplasia Versus Reflux Progressive scarring and renal failure were once considered chronic parenchymal infection (so-called chronic pyelonephritis) and were regarded as a consequence of VUR. However, in the 1980s, there was a retreat from the paradigm of the primary role of infection, and emphasis was placed on scarring as a result of reflux and the progressive nature of the glomerular lesion associated with glomerular hypertension (or hyperfiltration), so-called reflux nephropathy.^{3,17-19} The emphasis is changing again to the concept that scarring is often a consequence of renal dysplasia and that the reflux is a secondary feature (Fig. 50.3). Thus, irregular kidneys with normal-caliber ureters are more likely to be caused by primary dysplasia, and there may be no evidence of VUR.

Renal Scarring in Adults A practical clinical problem is the differential diagnosis of scarred, asymmetric kidneys. With older patients, the differential diagnosis of scarred or “lumpy bumpy” kidneys widens. Whereas this appearance was often attributed to analgesic nephropathy in the 1970s, today it is often designated reflux nephropathy. In older patients, multiple scarring from atheromatous arterial disease and embolization of the kidney is an increasingly important cause of renal failure. The diagnosis can be made by the radiologic features on IVU, but in practice, patients often have advanced renal impairment and are unable to excrete enough radiocontrast to delineate the anatomy of the calyces and pelvis and their relationship to the scarring. With

Figure 50.4 Differential diagnosis of “lumpy bumpy” kidneys from appearances on intravenous urography. **A**, Sickle cell disease: papillary necrosis. Missing papillae leave a round hole in the medulla (arrow) and give a clubbed appearance. Otherwise, the calyceal architecture is relatively well preserved. **B**, Reflux nephropathy. There is gross scarring and distortion of the calyceal pattern of the right kidney, giving rise to clubbed appearance of the dilated calyces. With reflux, there is a predilection for scarring of the upper and lower poles; with papillary necrosis or analgesic nephropathy, changes are less predictable. **C**, Analgesic nephropathy: the uniformly small shrunken kidney has relative preservation of the calyceal pattern. A plain film showed areas of calcification in both kidneys.

urologic conditions, there will be distortion and clubbing of calyces; with other conditions, the calyceal pattern should be normal, except for examples of papillary necrosis (Fig. 50.4). Scarring is best demonstrated by ^{99m}Tc -labeled dimercaptosuccinic acid (DMSA) scintigraphy.

Absent Kidneys

Unilateral Renal Agenesis

Complete absence of one kidney occurs in 1 in 500 to 1000 births. It can be familial, and the term *hereditary renal aplasia* is used by pediatricians. It is an autosomal dominant trait with incomplete penetrance and variable expression and can be associated with bilateral renal agenesis or severe dysplasia. In some families, mutations in uropodkin IIIa are found.²⁰

Typically, there is no ureter, and the ipsilateral half of the bladder trigone is missing. The remaining kidney is usually hypertrophic, but it may be ectopic, malrotated, or hydronephrotic with a megaureter. The more severe the dysplasia of the remaining kidney, the earlier the presentation. The ipsilateral testis and seminal tract are usually absent, and in 10% of cases, the adrenal gland is also missing. Girls can have an absent fallopian tube or ovary or malformation of the vagina or uterus. Other associations include imperforate anus and malformations of the vertebrae and cardiovascular system. Agenesis could result from failure in formation of either the metanephros or the ureteral bud; however, in association with cloacal abnormalities, the latter is more likely.

Normality of the single kidney should be confirmed by ^{99m}Tc -DMSA scintigraphy, normal isotopic GFR, and absence of proteinuria. If the remaining kidney is not normal, lifelong follow-up is necessary. Ultrasound scanning of the kidneys is recommended in first-degree relatives in all families in which there is an individual with unilateral or bilateral renal agenesis.

Bilateral Renal Agenesis

Bilateral renal agenesis is lethal. It is associated with pulmonary hypoplasia and a characteristic facial appearance (Potter facies) caused by intrauterine compression, which is a consequence of oligohydramnios. The prevalence is about 1 in

Figure 50.5 Single pelvic kidney. MRI scan, transverse section, showing single midline pelvic kidney. (Courtesy Dr. A. Kirkham, University College Hospitals, London, UK.)

10,000, with risk for occurrence in siblings of about 3%, unless there is a family history of agenesis, when risk rises to 15% to 20%.

Misplaced Kidneys

Renal Ectopia, Malrotation, and Crossed Fused Kidneys

The starting position of the fetal kidney is deep in the pelvis. Kidneys that fail to ascend properly and therefore remain lower than usual occur in 1 in 800 births (Fig. 50.5, see also Fig. 5.19). During development and ascent of the kidney, the renal pelvis comes to face more medially. The most common anomaly is for the pelvis to face forward. The more ectopic the kidney, the more severe the rotation and abnormal the appearance. In more than 90% of ectopia, there is fusion of both kidneys. This is now best visualized on CT or MR urography (Fig. 50.6). Symptoms and complications, if any, are caused by associated reflux or PUJ obstruction.

Figure 50.6 Crossed fused ectopia. **A**, MRI scan showing fused kidneys on right. **B**, There are two ureters (arrows). (Courtesy Dr. A. Kirkham, University College Hospitals, London, UK.)

Horseshoe Kidney

If both kidneys are low, they may join at the lower pole and are usually drained by two ureters (Fig. 50.7). They lie lower than normal, and further ascent is prevented by the root of the inferior mesenteric artery. This occurs in 1 in 400 to 1800 births and is more common in males (2:1). Patients present, if at all, with complications of reflux, obstruction, or stone formation.

Calyceal Abnormalities

Hydrocalyx and Hydrocalycosis

Dilated calyces are usually caused by obstruction. Focal dilation can also be caused by congenital infundibular stenosis, extrinsic compression from vessel or tumor, stones, or tuberculosis. If obstruction is excluded, the appearance is likely to be a congenital abnormality and can be an incidental finding. Moreover, if the GFR is normal and the divided function of the kidneys is 50:50, surgery to “improve” the anatomy should not be attempted.

Figure 50.7 Horseshoe kidney. **A**, IVU soon after pregnancy in a 25-year-old woman shows not only the horseshoe kidney joining in the midline but also dilated ureters as a transient consequence of pregnancy. **B**, Dimercaptosuccinate scan showing a horseshoe kidney.

Megacalycosis

In megacalycosis, there is bizarre dysplasia of the calyceal system with an increase in the number of calyces. There is no obstruction, and it results from malformation of renal papillae. Megacalycosis is congenital, usually unilateral, and an incidental finding. It is much more common in males (6:1) and occurs only in Caucasians.

Bilateral disease is confined to males, and segmental, unilateral disease to females, which suggests an X-linked partially recessive gene with reduced penetrance in females. There may be an associated ipsilateral segmental megaureter, usually affecting the distal third.

Calyceal Diverticulum (Calyceal Cyst)

A calyceal diverticulum is a cavity peripheral to a minor calyx that is not a closed cyst but is connected to the calyx by a narrow channel. It is usually an incidental finding in 5 per 1000 IVUs and is best seen on a delayed film (Fig. 50.8). If it is present, symptoms relate to stones or infection within the cavity.

Bardet-Biedl Syndrome

Multiple calyceal clubbing and calyceal diverticula are the characteristic features of the renal dysplasia seen in Bardet-Biedl

Figure 50.8 Calyceal cyst. IVU showing an upper pole calyceal cyst filled with contrast (arrows). The plain abdominal film showed a group of stones in the floor of the cyst.

syndrome (formerly known as Laurence-Moon-Biedl syndrome).²¹ This autosomal recessive condition is characterized by retinitis pigmentosa, dysmorphic extremities (sometimes with polydactyly), obesity, and hypogonadism. Calyceal malformation is associated with parenchymal dysplasia; renal failure in early adult life is common.

Bardet-Biedl syndrome is probably the result of a lack of cilia formation or function caused by a defect of the basal body of ciliated cells. It is due to a mutation the *TTC8* gene which encodes a protein with a prokaryotic domain, pilF, involved in pilus formation and twitching mobility.²²

Pelviureteral Junction Obstruction

PUJ obstruction is one of the most frequent causes of obstructive uropathy in children. The condition is usually congenital but can have an acquired mechanical basis caused by stenosis or external compression from adhesions, aberrant lower pole vessels, or kinking of the most proximal ureter. Associated abnormalities are common, and up to 50% of infants have another urologic abnormality, such as contralateral PUJ, contralateral renal dysplastic and multicystic kidney, minor degrees of VUR, and contralateral renal agenesis.

Older children can present with an abdominal mass or with pain in the flank, hematuria secondary to mild trauma, or UTI. Hypertension is unusual but can occur temporarily after surgical correction.

Diagnostic procedures have to differentiate between significant obstruction (Fig. 50.9) that requires surgical correction and congenital ectasia of the renal pelvis, in which case surgery is not indicated. Indications for surgical intervention include impairment of renal function, pyelonephritis, renal stones, and pain. Kidneys with good function can generally be left alone, and surgery is indicated only when function is clearly shown to deteriorate.²³

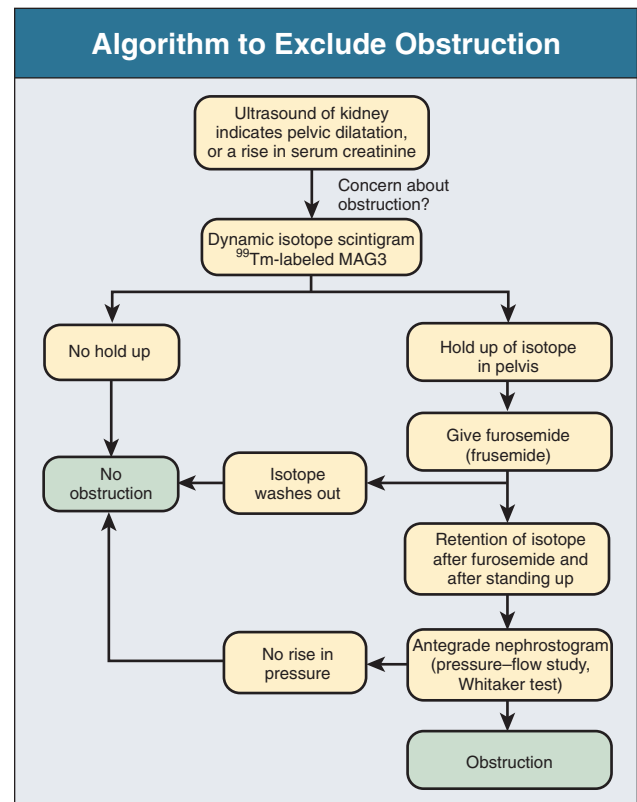

Figure 50.9 Algorithm to exclude obstruction.

Gonadal Dysgenesis

The problems of intersex, gender identity, and micropenis are beyond the scope of this chapter and rarely encountered in adult practice. Patients will be met, however, with ESRD who are phenotypically female but are genotype XY and have mutations of *WT1* (Denys-Drash and Frasier syndromes). They have gonadal dysgenesis and must have their streak ovaries removed; otherwise, gonadoblastomas will develop.

URETERAL ABNORMALITIES

Duplex Ureters

Duplication of the ureter and the renal pelvis is a common anomaly, with an incidence of about 1 in 150 births; unilateral duplication is six times more frequent than bilateral. It is more common in girls. If duplication has been detected in a patient, the likelihood of another sibling with duplication rises to 1 in 8.

Pathogenesis

If the ureteral bud bifurcates after its origin from the mesonephric duct but arises at a normal site, an incomplete ureteral duplication with a Y ureter will develop.⁷ Complete ureteral duplication occurs if there are two ureteral buds, one in the normal location and the other in a low position. The normal bud ends in a correct site on the trigone in the bladder and is nonrefluxing. The lower bud, representing the ureter of the lower pole of the kidney, ends in the bladder as a lateral orifice with a short submucosal tunnel. The lower pole ureter is therefore often associated with VUR, and scarring of the lower pole can result.

If there are two ureteral buds, one with a normal location and one with a high position, the upper ureter is incorporated into the developing bladder, ending more distally and medial to the normal one. Thus, the upper pole ureter ends ectopically, and as a consequence of either obstruction or dysplasia, there is often severe scarring of the upper pole moiety.

Clinical Manifestations

In most adult patients, ureteral reduplication is asymptomatic and causes no long-term problems. Children with ureteral duplication often have VUR. The spontaneous disappearance of reflux is less common in duplex ureters than in patients with a single ureter.²⁴ Duplex ureters are best diagnosed by IVU and cystoscopy. PUJ obstruction of the ureter draining the lower pole of the kidney can occur.

Associated conditions, such as ectopic ureters and ureterocele (see later discussion), usually cause problems in early life and therefore have been dealt with by adolescence. Upper pole scarring is associated with an ectopic ureter, lower pole scarring with VUR (Fig. 50.10A).

Ectopic Ureters

Ectopic ureters are almost always associated with ureteral reduplication, and 10% are bilateral. There is a female to male ratio of 7:1. The ectopic ureter comes from the upper pole and inserts into the bladder more distally and toward the bladder neck, or it opens into the upper urethra. In females, the ureter may end in the urethra, vagina, or vulva, and patients present with incontinence, UTIs, or a persistent vaginal discharge, particularly if the external sphincter is damaged, for example, during labor.

Ectopic ureters are rare in males and present as UTI. Usually, there is a single ureter associated with a dysplastic kidney, which ends in the posterior urethra, ejaculatory duct, seminal vesicle, or vas. Males are usually continent because the ureter is proximal to the external sphincter.

Ectopic ureters are best visualized by IVU, although a small dysplastic kidney may be missed. A micturating cystourethrogram shows reflux into the lower pole of the kidney in 50% of patients.

Ureterocele

Ureteroceles are cystic dilations of the terminal segments of the ureter and are caused by maldevelopment of the caudal ureter. They occur more commonly in females (4:1) and almost exclusively in Caucasians, and 10% are bilateral.

Ectopic ureters and ureters with ureteroceles frequently (80%) drain the upper pole and are often associated with dysplastic or nonfunctional renal tissue. They usually present in childhood with infection; when large, they can obstruct the bladder neck or even the contralateral ureter. In adults, they commonly present with stones in the lower ureter. The treatment of simple ureteroceles is surgical excision with reimplantation of the ureter or simple incision if they subtend a well-functioning moiety. There are usually no medical sequelae.

Megaureter

Isolated dilation of the ureter does not necessarily imply obstruction. There are three broad groups of conditions with widely dilated ureters:

1. Obstruction of the ureter itself. This may be intrinsic (e.g., stone) or extrinsic (e.g., retroperitoneal fibrosis); it is not associated with reflux.

Figure 50.10 Duplex kidney. **A**, IVU shows a duplex left kidney. The lower pole is scarred and shows evidence of reflux damage. The two ureters entered the bladder separately, with the lower pole ureter in the abnormal location. The right kidney also shows features of reflux, with clubbing of the calyces and some scarring. **B**, CT scan showing an isolated right-sided megaureter (arrows).

2. Bladder outflow obstruction, with secondary ureteral obstruction. Examples include a neuropathic bladder and posterior urethral valves; this may or may not be associated with reflux.
3. A dilated but nonobstructed ureter. This often occurs without reflux, and there can be normal renal function; sometimes, this is caused by an adynamic segment of the lower ureter (Fig. 50.10B).

Pathogenesis

In the normal ureter, there is a characteristic helical orientation of muscle fibers. When the megaureter is secondary to bladder outflow obstruction, there is muscle hyperplasia and hypertrophy of the ureteral wall. In megaureters for which there is no apparent cause, a variety of abnormalities of muscle orientation are described, or there may even be absence of muscle fibers at the proximal end of the undilated segment.

Electron microscopy shows an increase in collagen between the muscle bundles at the level of the obstructing segment.²⁵ Obstruction appears to be caused by a failure of peristalsis through the distal ureteral segment.

Clinical Manifestations

Most cases of megaureter associated with obstruction present in childhood with severe infections, often complicated by septicemia. In such cases, there is a high incidence of other congenital abnormalities. In less severe cases or when there is no obstruction, patients can present with abdominal pain, loin pain, hematuria, and UTI. Renal stones can form easily in the dilated systems. The exclusion of obstruction is often established only by an antegrade pressure-flow study (Whitaker test), in which a nephrostomy is placed in the renal pelvis and contrast material infused at 10 ml/min.²⁶

Treatment

A definite diagnosis (is there obstruction or not?) must be made (see Fig. 50.9). The current view is that patients with non-obstructed asymptomatic disease should be managed conservatively, and most do very well with this approach.

BLADDER AND OUTFLOW DISORDERS

Prune-Belly Syndrome

The prune-belly syndrome occurs in males and consists of absence of the muscles of the anterior abdominal wall, bizarre malformations of the urinary tract with gross dilation of the bladder and ureters, and bilateral undescended testes.²⁷⁻²⁹ When it is diagnosed early, renal outcome is related to the degree of renal dysplasia. There are incomplete forms of the syndrome (pseudo-prune). Rarely, a similar megacystis or megaureter may be seen in either sex.

Pathogenesis

No gene defect or unifying hypothesis has emerged to explain these features. The incidence varies from 1 in 30,000 to 50,000. There are a few familial cases, and the condition has been reported in twins, but there is 100% discordance reported in identical twins, which is a powerful argument against a genetic basis. There is evidence for a primary, localized arrest of mesenchymal development. This is supported by the lack of prostatic differentiation; the epithelial element in the prostate is absent or hypoplastic. Ultrastructure studies of the ureter show massive replacement of smooth muscle with fibrous and collagen tissue and the absence of nerve plexuses. A nearly identical syndrome can occur as a consequence of fetal urethral obstruction, including urethral atresia.

Clinical Manifestations

The prognosis is dependent on the degree of renal dysplasia and injury. Three groups can be distinguished. In group I, complete urethral obstruction causes stillbirth or neonatal death (20%); in group II, acute, early presentation requires diversion and reconstruction (20%); in group III, good health and renal function continue despite urologic appearances (60%).

There is complete absence or incomplete formation of the rectus abdominis and other muscles, which leads to the wrinkled abdominal wall of the prune infant (see Fig 50.12C). This gives way to a fairly smooth “pot belly” in later life (Fig. 50.11). Reconstructive surgery is not normally required. The patients grow up physically active and strong but cannot sit up directly from a supine position. Abnormalities of the thoracic cage, such as pectus excavatum, are common.

Although true outflow obstruction is sometimes present, the gross and irregular dilation of the urinary tract that is character-

Figure 50.11 Prune-belly syndrome. Note the lax abdominal musculature leading to a pot-bellied appearance. There is also marked thoracic cage deformity. (Courtesy Prof. C. R. J. Woodhouse, University College Hospital, London, UK.)

istic of this syndrome is primarily caused by a developmental defect with a variable degree of smooth muscle aplasia leading to aperistaltic ureters (Fig. 50.12). Urodynamic studies are often difficult to interpret because of gross VUR, but typically there is a low-pressure bladder. With late presentation, some patients have detrusor instability.

Differential Diagnosis

In severe cases of megacystis or megaureter with gross impairment of renal function (often with dysplastic kidneys), the differential diagnosis includes posterior urethral valves, renal dysplasia with or without multiple congenital defects, neuropathic bladder, and nephrogenic diabetes insipidus.

Natural History

Once any outflow obstruction is dealt with, usually in infancy, the renal function should remain stable despite the frightening radiologic appearances. In those patients observed in our unit for up to 40 years, renal deterioration and hypertension have been rare. In the small number who have progressed, recurrent infection, hypertension, and proteinuria have been warning signs of impending trouble.

Renal scarring should be assessed by isotopic DMSA scintigraphy and renal function followed by serial isotopic GFR measurements. Lifelong attention to blood pressure, UTIs, and stones is necessary.

Treatment

In all children, even with good renal function, there should be a careful search for obstruction, beginning with the urethra and working up to the PUJ, but often no obstruction is found and no surgery is required. In many others, the floppy bladder is not anatomically obstructed, but bladder emptying is improved by urethrotomy (“functional obstruction”). In infancy, there is debate about the need for reconstructive surgery. There is

Figure 50.12 Prune-belly syndrome. **A**, Typical IVU appearance of a patient with prune-belly syndrome and good renal function. Often, the ureters are extremely dilated and tortuous. **B**, CT urogram showing gross bilateral hydronephrosis. **C**, Absence of anterior abdominal wall musculature (arrows).

certainly a group of patients born with severely compromised renal function who do require reconstruction after stabilization by early diversion.³⁰

The current view is that the testes should be brought down to the scrotum in infancy. It is hoped that earlier surgery will produce proper germ cell development and thus preserve fertility. So far, however, no prune-belly patient has been shown to be fertile.

Bladder Exstrophy (Ectopia Vesicae)

Classic exstrophy is the failure of the anterior abdominal wall and bladder to close, but there are a range of defects from epispadias of an otherwise normal penis to major cloacal abnormalities (Fig. 50.13).

Pathogenesis

Failure of growth of the lower abdominal wall between the allantois and the urogenital membrane coupled with breakdown of the urogenital membrane leaves a small, open bladder plate, a low-placed umbilical root, and diastasis of the pubic bones (Fig 50.14B). The genital tubercle is probably placed lower in these patients, and the cloacal membrane ruptures above it, leading to a penis with an open dorsal surface that is continuous with the bladder plate. A midline closure defect causes a failure of fusion of the lower anterior abdominal wall, including the symphysis pubis, lower urinary tract, and external genitalia. There are rare reports of a familial incidence. The condition occurs in 1 in 10,000 to 50,000 births. The male to female ratio is 2:1.

Clinical Manifestations

In severe cases, the bladder mucosa lies exposed on the lower abdominal wall, with the bladder neck and urethra laid open. The prostate and testes are normal. Most patients have normal kidneys at birth (although many reports do not record the state of the kidneys at birth). In one series, 33% had dilated ureters at presentation, but IVU was usually normal after diversion. However, in another series, one third of patients were said to have unilateral renal agenesis.³¹ Renal function may be preserved after the diversion, although reflux is common (Fig. 50.14).

Other congenital abnormalities are only rarely present. More severe cloacal abnormalities are associated with imperforate anus and either high or low rectal atresia.

Figure 50.14 Cystography in bladder exstrophy. **A**, A 26-year-old woman with bladder exstrophy who has a continent Mitrofanoff system with use of the colon to create a reservoir. There is reflux into the left kidney. There is also reflux into the right kidney, but the kidney is obscured by the full reservoir. Her GFR is 130 ml/min. **B**, MRI scan of patient with bladder exstrophy showing small scarred left kidney with several renal calculi (arrow). Note widely splayed symphysis pubis.

Natural History

Long-term renal outcome depends on the bladder. In the long term (up to 25 years), the kidneys survive much better with a well-functioning bladder; 13% of those with a good bladder had significant renal damage compared with 82% with ileal conduits, 22% with nonrefluxing colonic conduits, and 33% with ureterosigmoidostomy.³² Today, the bladder is usually augmented (enterocystoplasty, ileocystoplasty, cecocystoplasty) or replaced by bowel (intestinal reservoir). In a study of 53 such patients who were observed for more than 10 years, renal function deteriorated (fall in GFR of 20% or more) in only 10 (20%).³³

Treatment

When the infant is born, the three urologic treatment goals are to close the abdominal wall, to establish urinary continence and preserve renal function, and to reconstruct cosmetically acceptable genitalia.

Figure 50.15 Epispadias. Result of multiple surgeries to close the epispadias and to lengthen the penis. (Courtesy Prof. C. R. J. Woodhouse, University College Hospital, London, UK.)

Causes of Neuropathic Bladder	
Site of Lesion	Causes
Cerebral	Cerebrovascular accident/cerebral palsy, encephalopathy, trauma, Parkinson's disease, dementia
Spinal	Isolated (no other neurologic features), trauma, multiple sclerosis, compression, spina bifida, spinal dysraphism, tethered cord, sacral agenesis, sacral teratoma
Peripheral nerve	Pelvic surgery, diabetes

Figure 50.16 Causes of neuropathic bladder.

The aim of initial surgery is to convert the defect to a complete epispadias (Fig. 50.15). At 4 years of age, reconstruction of the bladder neck and correction of the epispadias can be performed. If the bladder is small, intestinal augmentation is required. Patients may be able to void, but many have to use catheters. Incontinence may be a long-term problem.

Neuropathic Bladder

In childhood, the most common cause of a neuropathic bladder is myelomeningocele. A neuropathic bladder may also be seen without associated neurologic or other obvious causes (Fig. 50.16). The principal consequences are incontinence, infection, and reflux with upper tract dilation and subsequently renal failure. Early urodynamic assessment is essential (Fig. 50.17). Three different patterns of bladder behavior are seen: contractile, intermediate, and acontractile.

Contractile Behavior

An overactive detrusor (hyperreflexia) can produce some bladder emptying (incontinence). Unfortunately, 95% of patients have sphincter dyssynergia (inability to relax urethral sphincter), which results in no relaxation and incomplete emptying of the bladder. Patients with incomplete lesions may have some control of the distal sphincter and normal anal and sacral reflexes. Ironically, although this latter group has the least neurologic deficit, they have the worst bladder situation, generating high pressures

Figure 50.17 Urodynamic assessment by cystometrography. The vesical pressure is measured simultaneously with the abdominal pressure through the rectum; the detrusor pressure is the difference. A cough is used as a marker to show that the system is working. During filling, the first desire to void is normally at a detrusor pressure of less than 10 cm H₂O. This point is noted. The voiding pressure should normally be less than 40 cm H₂O (and is lower in women). Detrusor instability is an unstable (spontaneous) contraction occurring with a detrusor pressure above 15 cm H₂O. Higher pressure can cause incontinence. In combination with radiologic imaging (videocystometrography), the following are recorded: bladder neck, closed or open; bladder pressure, end filling; voiding detrusor pressure; bladder stability; compliance; flow rate, maximum; sensation, first; volume, voided and residual. (Courtesy Prof. M. Craggs, University College London, UK.)

and great risk for renal injury. The bladder becomes progressively hypertrophic, fibrotic, and poorly compliant.

Intermediate Behavior

These patients have some detrusor activity, but not sufficient to empty the bladder. Their bladders are poorly compliant, and they have no voluntary control of their sphincters, so any rise in bladder pressure tends to cause incontinence, or the high intravesical pressures lead to renal injury.

Acontractile Behavior

In about 25% of patients, there is no detrusor activity, and the bladder overflows when it is sufficiently full. This is not usually associated with renal failure.

Myelodysplasia

Myelodysplasia refers to a group of neural tube anomalies that primarily affect the lumbar and sacral segment of the spinal cord and are the most common cause of neurogenic bladder dysfunction in children. Spina bifida means the defective fusion of the posterior vertebral arches. Meningocele implies that the meninges extend beyond the confines of the vertebral canal with no neural elements contained inside. A myelomeningocele has neural tissue protruding with the meningocele. Spinal dysraphism (symptomatic spina bifida occulta) defines a group of structural anomalies of the caudal end of the spinal cord that do not result in an open vertebral canal but are associated with incomplete fusion of the posterior vertebral arches. Sacral agenesis is a rare anomaly in which part or all of two or more vertebral

bodies is absent. It occurs early in fetal development when there is failure of ossification of the lowest vertebral segments. The only known teratogen is insulin. Sacral agenesis occurs in 1% of children born to insulin-dependent mothers. Partial sacral agenesis can be associated with an anterior meningocele.

Pathogenesis

The neural tube normally forms as the neural folds close over and fuse, starting in the cervical region and progressing caudally. It is believed that the embryologic defect is an incomplete tubularization of the neural tube, with inadequate mesodermal invagination and subsequent arrest of vertebral arch formation.

The incidence of myelodysplasia varies from 1 to 5 in 1000 live births, but there are wide geographic variations. Monozygotic twins are often discordant for spina bifida, but siblings are at increased risk (1:10–20), and children of affected parents have a 4% chance of having a similarly affected child. Myelomeningocele accounts for more than 90% of myelodysplastic infants. Folic acid supplements taken during the last trimester reduce the incidence of myelodysplasia by 50%.

Clinical Manifestations

All causes of tethered cord can produce a variable neurologic deficit. During development, some children develop progressive neurologic disturbance with bladder dysfunction, bowel dysfunction, scoliosis, and a syndrome of pes cavus and limb growth failure.

Bladder Dysfunction Neuropathic bladder can be an isolated problem with abnormal urodynamic studies but a normal neurologic examination.³⁴

Bowel Dysfunction Bowel dysfunction is often present and needs to be treated accordingly. There may be severe constipation and overflow incontinence. The antegrade continent enterostomy procedure has been developed to improve the management. The appendix is brought out to the abdominal surface, and thus the colon can be irrigated antegradely with saline.

Intelligence Patients with myelomeningocele may have some intellectual impairment, especially those who have required ventriculoperitoneal shunting for associated hydrocephalus. Manual dexterity may also be affected. These are very important issues in long-term management.

Natural History

About 14% of patients have renal complications at birth and are at high risk in the next few years. Ultimately, about 50% will develop upper tract problems, although these can take up to 30 years to occur (Fig. 50.18). In one prospective study, renal outcome could be predicted by the urodynamic findings, with worst outcomes related to increased bladder wall thickness, degree of reflux, urethral pressures above 70 cm H₂O, and reduced bladder capacity. VUR occurs in 3% to 5% of newborns with detrusor hypertonicity or dyssynergia. Without treatment, this increases to 30% to 40% by the age of 5 years.³⁵

Treatment

The management of the bladder depends on the urodynamic findings. In the 1970s, clean intermittent self-catheterization (CISC) was introduced,³⁶ but before that time, urinary diversion was the usual treatment. Today, when reflux and hydroureter are

Figure 50.18 Sacral spina bifida with neuropathic bladder. **A**, IVU shows evidence of a previous hydronephrosis and subsequent scarring of the right kidney. The architecture of the left kidney is well preserved. **B**, Micturating cystogram. The typical tapering, hypertrophied, trabeculated bladder giving the characteristic fir cone appearance. Note the gross reflux on the right side. This is probably helping to protect the left kidney by acting as a pop-off mechanism. This is analogous to the protection that can occur in boys with posterior urethral valves.

present, the management is principally with CISC and anticholinergic drugs that increase bladder compliance.³⁷

Bladder Neck Obstruction

Congenital bladder neck obstruction is rare and is usually caused by a neuropathic bladder, posterior urethral valves, or an ectopic ureterocele.

Posterior Urethral Valves

Posterior urethral valves are the most common cause of severe subvesical obstruction in the male infant (although in the newborn, they account for only 10% of cases of hydronephrosis). As a consequence, bilateral hydronephrosis and megaureter occur. Obstruction is caused by a diaphragm that extends from the floor to the roof of the urethra at the apex of the prostate. Valves appear as mucosal folds in the posterior urethra below the verumontanum. There is dilation of the proximal urethra and bladder wall hypertrophy and trabeculation. Above the valves, there is dilation of the prostatic urethra, which undermines the bladder neck. The valves obstruct flow only in one direction, and therefore a catheter can be passed without difficulty.

Pathogenesis

The urethra develops in two parts: differentiation of the urogenital sinus part (posterior urethra) and tubularization of the urethral plate (anterior urethra). Early obstruction during renal development can result in severe renal dysplasia.

Clinical Manifestations

Most cases of posterior urethral valves are now detected antenatally by ultrasound. Half of all patients present before the age of 1 year. Infants present with a palpably distended bladder and enlarged kidneys, abnormal urine stream, or failure to thrive due to renal failure. At diagnosis, 30% to 50% of children also have VUR. Children with less severe disease present with poor stream, hematuria, incontinence, acute UTI, or renal failure; however, late presentation is also associated with worse outcome.³⁸

There are three abnormal features that can help protect the kidney; these all act to reduce the high pressures generated during voiding. They are massive unilateral reflux, usually with ipsilateral renal dysplasia (thereby protecting the other kidney); large bladder diverticulum; and urinary extravasation, often with urinary ascites. These protective mechanisms are referred to as “pop-off” mechanisms (see Fig. 50.18).³⁹ Ultrasound can show the bladder thickening, dilated system, and dilation of the posterior urethra. A specific diagnosis should be documented by videocystometrography (see later discussion).

Natural History

In the 1960s, 25% of children died within the first 12 months, and 25% died later in childhood, including “renal death” (i.e., ESRD). By the late 1990s, the early mortality rate was less than 5%, and after 15 years of follow-up, only 15% to 20% of patients had reached ESRD.⁴⁰

The bladder may become stretched, resulting in poor emptying, or unstable, leading to poor compliance, unsuppressed detrusor contractions, and high storage pressure. Both these situations are exaggerated by progressive polyuria. It is not uncommon for such patients to have a daily urine volume of 5 liters. Urodynamic follow-up studies suggest that instability decreases with time; bladder capacity increases, but there are unsustained voiding contractions. The prognosis correlates with the nadir serum creatinine value once obstruction has been relieved. Despite adequate early treatment, chronic kidney disease (CKD) due to renal dysplasia develops in many children.^{38,41}

Treatment

All children have had transurethral resection of their valves in infancy. Bladder diversion should be avoided. The question of “undiversion” of ileal conduits (created in earlier times) is

discussed later. Bladder instability and poor bladder compliance must be treated, irrespective of whether they are causing symptoms. Boys with substantial residual volumes can be managed by CISC, but there is often poor compliance with this either because of urethral discomfort or because previous urethral surgery has made the passage of catheters difficult. Compliance is a particular problem with adolescents who are continent and for whom renal failure is too abstract a concept. Continence often improves spontaneously at puberty but can be helped by imipramine. Deterioration in renal function will require further examination of urine flow rate and exclusion of urethral stricture.

Urethral Diverticulum

Urethral diverticulum usually occurs in boys and is rare. It may present with UTI, obstruction, or stones. There are two types, anterior and posterior. The anterior type can be associated with anterior urethral valves and obstruction.

GENERAL MANAGEMENT OF CONGENITAL TRACT ABNORMALITIES

The principles of management of congenital tract abnormalities are shown in [Figure 50.19](#). The most important part of the management is ensuring that the patient, family, and primary care physician know what can and must be done. The first thing to make clear is the necessity of long-term follow-up at no longer than annual intervals. ESRD commonly occurs when a patient is lost to follow-up, often presenting later with accelerated hypertension and rapid loss of renal function.

Clinical Evaluation

By the time the adolescent is passed on to an adult physician, it is assumed that the urinary tract is not obstructed and further surgery is not required. Nevertheless, it is the responsibility of the nephrologists and urologists who care for these children to review this aspect from time to time.

Symptomatic UTI is common and must be treated promptly. Increase in frequency or severity of infections must lead to

investigations to find the cause.⁴² The blood pressure must be monitored regularly and kept normal. Finally, renal function must be monitored, proteinuria assessed, and the cause of any deterioration identified. As in any other renal condition, the remnant kidney function may decline inexorably, and this is associated with increasing proteinuria and hypertension. As with other renal conditions, function is usually stable when there is little or no proteinuria. Deterioration in the absence of proteinuria must alert the physician to the likelihood of obstruction or the adverse effect of a nephrotoxic drug.

A number of routine investigations should be performed to document the current situation and to act as a reference point for the future ([Fig. 50.20](#)). If the bladder empties completely with an adequate flow rate (15 ml/s), no problems should arise. If there is any doubt about the condition of the bladder, urodynamic investigations are necessary. If the clinical situation changes, further investigations are required. An increase in UTIs might suggest a stone or increase in residual urine. With an unexpected decline in renal function, obstruction has to be excluded all over again.

It is helpful and important for the patient to keep a 24-hour urine volume diary every 6 to 12 months. Patients are asked to write down the time that they voided and to measure and record the volume passed. It is best to ask them to do this on 2 consecutive days, so that one can determine the maximum bladder capacity and the total 24-hour urine volume. This should be done before urodynamic investigations because results can be misleading if bladder is not filled to capacity.

Exclude Obstruction

Obstruction must always be excluded if there is a change in renal function. The possibility of obstruction may be raised by a routine ultrasound (see [Fig. 50.9](#)) and should be pursued with MAG3 scintigraphy to exclude obstruction ([Fig. 50.21](#)).

In patients with conduits, obstruction can be excluded by infusion of contrast material into the loop (loopogram) and demonstration of reflux up the ureter.

Rarely, in patients with large bladders or in transplant recipients, the kidney may become obstructed when the bladder reaches a certain volume. This can be investigated by filling the

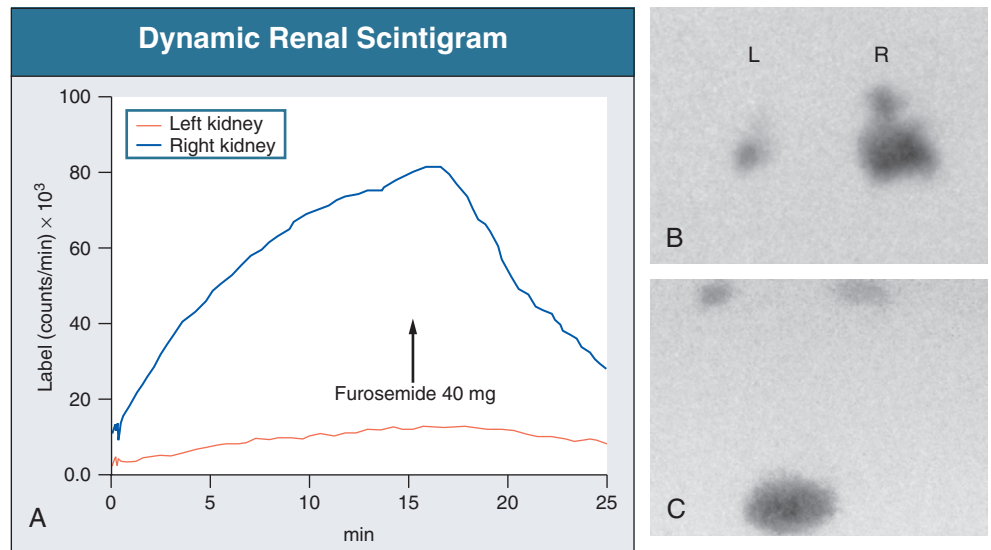

Management of Congenital Renal Tract Abnormalities
Educate and explain to encourage compliance
Review urologic status
Find cause of urinary tract obstruction and treat
Control blood pressure
Monitor renal function and proteinuria
Treat acidosis
Prevent bone disease
Check for stones
Clean intermittent self-catheterization for chronic retention
Maintain bladder storage pressure below 40 cm H ₂ O
Maintain bladder volume below 400 ml

Figure 50.21 Dynamic ^{99m}Tc -labeled MAG3 renal scintigram. **A**, Time-activity curve showing accumulation of isotope in right kidney that washes out after furosemide, thus excluding significant obstruction. **B** and **C**, Images from the same study showing holdup of isotope in dilated right renal pelvis (**B**) that washes out into the bladder after furosemide (**C**), excluding significant obstruction.

bladder by a catheter and performing ^{99m}Tc -labeled MAG3 scintigraphy, initially with the bladder full. If there is no excretion, the bladder volume can be reduced in 100-ml increments until there is flow down the ureter (Fig. 50.22).

Urodynamics

Any urodynamic investigation should start with a free urine flow rate. Provided the flow rate is normal and the bladder empties completely (leaving no residual volume on postmicturition ultrasound), it can be assumed that there is no significant bladder outflow obstruction.

Complete investigation of abnormalities of bladder and urethral function requires synchronous recordings of intravesical and intrarectal pressures taken during bladder filling and emptying (see Fig. 50.17). Combined with radiologic imaging, the study is known as videocystometrography.

Surgical Correction of the Urinary Tract

A normal bladder acts as a low-pressure, good-volume urine reservoir that is continent, is sterile, and empties freely and completely. Any other form of urine reservoir aims to recreate such an environment. When this is not achieved in either a natural or a reconstructed bladder, complications such as sepsis and renal dysfunction can occur.

A variety of conduits and continent reservoirs have been developed to replace unusable bladders. Ileal conduit diversion has been most widely used for native kidneys, although deterioration in renal function commonly occurs secondary to long-term complications including urosepsis, renal calculi, and, most commonly, stenosis leading either to obstruction or to reflux with ureteral dilation. There is an overall complication rate of 45%, but with a high index of suspicion and an aggressive diagnostic and therapeutic approach, many of these problems can be detected and treated early, with resultant good long-term function of native kidneys. Similar results may be obtained when renal transplantation is performed in these patients.⁴³ Other forms of urinary diversion that are continent and therefore more socially acceptable to patients are now widely used in general urologic practice and are being encountered in renal transplantation (Fig. 50.23; see also Fig. 50.14). These forms include aug-

mented bladders draining through the urethra and augmented or intestinal bladders draining through continent stomas.

Undiversion of Conduits

The only certain improvement with undiversion is cosmetic. Initially, undiversion was undertaken because of poor results or complications from conduits. Short-term results of undiversion are very promising, and the major indications today are convenience and cosmetic appearance (see Fig. 50.23). Long-term results, however, are not yet available.

Before undiversion is considered, four factors must be addressed:

1. Is there residual obstruction?
2. What is the function of the bladder?
3. What is the function of the sphincters?
4. What is the normal 24-hour urine volume?

In particular, the bladder storage pressure must be considered because a low-pressure reservoir must be achieved. This is a particular problem when patients are polyuric. The potential capacity of the bladder will often have to be reassessed after a period of bladder cycling, when the bladder is repeatedly filled through a suprapubic catheter and the volume, voiding capacity, and residual volume are determined. If the native bladder is not of sufficient volume and compliance, some form of augmentation will be required.

COMPLICATIONS

Urinary Tract Infections (To Treat or Not To Treat)

Symptomatic UTIs are common.⁴² Risk factors include stagnation of urine, stones, foreign bodies (stents, catheters), previous infections, and renal scarring. UTIs must be treated promptly after a urine culture specimen (midstream or catheter specimen) has been taken. Recurrent UTIs, particularly after a period of stability, must lead to further investigations to exclude stones or obstruction, including abdominal radiography, renal ultrasound, and postmicturition bladder ultrasound.

Asymptomatic UTIs often do not require treatment (except during pregnancy). For patients with urinary diversions, it is

Figure 50.22 Dynamic isotope scan (MAG3) starting with bladder full in a patient with solitary right kidney. **A**, Rising curve of tracer accumulating in kidney and showing no excretion. **B**, Accumulation of isotope in hydronephrotic pelvis without excretion to bladder. **C**, The 100-ml increments of fluid removed from bladder result in eventual free drainage of the kidney.

Figure 50.23 Mitrofanoff stoma. A patient born with bladder exstrophy who has had a successful renal transplant for the past 20 years. Her kidney is plumbed into a colonic reservoir, and she catheterizes herself through a continent Mitrofanoff stoma, which in the picture is covered by a small piece of bandage.

important to obtain a catheter specimen of urine because urine taken from a bag is invariably infected.

It is sometimes appropriate to give prophylactic antibiotics, such as trimethoprim or nitrofurantoin, to eradicate infection. Many patients believe that cranberry juice helps them; it reduces the incidence of *Escherichia coli* infection but will not treat a symptomatic infection. Tetracycline and oxytetracycline are

contraindicated because they cause acute on chronic deterioration in renal function; doxycycline, however, can be used. Nitrofurantoin and nalidixic acid are avoided if GFR is reduced below 50 ml/min because they are both renally excreted and toxic in renal failure. Quinolones should not be used for prophylaxis, if possible, because of the risk for inducing resistance. Attempts to sterilize the urinary tract when foreign bodies such as stones remain are unlikely to be successful.

If prophylactic antibiotics are no longer effective at preventing infection, it is advisable to stop all antibiotics and to give the patient a supply of antibiotics to treat symptoms at home as they occur.

Hypertension and Glomerular Hyperfiltration

If renal function is declining with proteinuria and hypertension, glomerular hyperfiltration is likely, although all other causes of renal dysfunction must be excluded. Patients should be treated with renin-angiotensin blockade (ACE inhibitors and angiotensin receptor blockers [ARBs]).⁴

Proteinuria and Progressive Renal Failure

Can progression to ESRD be predicted, and does treatment with ACE inhibitors delay or prevent this?⁴ We investigated this in a retrospective review of patients with scarred irregular kidneys

as a consequence of either primary renal dysplasia or abnormal bladder function. All patients had at least 5 years of follow-up, and when ACE inhibitors were started, estimated GFR (eGFR) was below 60 ml/min per 1.73 m² (mean, 41 ml/min), with mean proteinuria of 1.7 g/24 h. ESRD developed in 46% of the patients but in none with proteinuria less than 0.5 g/24 h and in only 2 of 18 patients with eGFR above 50 ml/min. The renal outcome of the two groups was similar whether there was primary renal dysplasia or abnormal bladder function. There was a watershed GFR of 40 to 50 ml/min above which ACE inhibitor treatment improved renal outcome.⁴ The similar outcome of the two groups indicates that progressive renal failure in young men born with abnormal bladders is due to intrinsic renal pathophysiologic processes, in contrast to the view that it is a consequence of poor bladder function.

Hypertension

Hypertension is common in the presence of scarred kidneys, but it is usually controlled easily with one or two drugs. Patients in whom CKD is secondary to obstruction tend to have volume contraction and therefore often have normal blood pressure or only mild hypertension. ACE inhibitors or ARBs are preferred for patients with proteinuria and progressive renal failure. Diuretics are likely to cause unacceptable side effects if the patient is volume contracted.

Stones

Stones that form in the presence of infected urine are typically magnesium ammonium phosphate (struvite) or calcium phosphate (hydroxyl apatite, carbonate apatite, calcium hydrogen phosphate [brushite], tricalcium phosphate [whitlockite]). These salts are poorly soluble in alkaline urine. In 90% of patients, the infecting organism is *Proteus* species,⁴⁴ but other urea-splitting organisms (including some staphylococci and *Pseudomonas* species) also generate ammonia.⁴²

Stones, usually calcium phosphate, are common in conduits because of the alkaline environment and occur in 5% to 30% of ileal conduits. Stones must be suspected if UTIs recur or become more frequent, if renal function suddenly deteriorates, or if there is an unexplained sterile pyuria.

Tubular Dysfunction

In patients whose renal failure is secondary to obstruction, there is significant tubular injury. This may cause problems, in particular with urinary concentration, acidification, and sodium reabsorption.

Polyuria

Nocturia is one of the most significant symptoms in the assessment of patients in whom obstruction or tubular dysfunction is suspected. Overfilling of the bladder or reservoir is an important cause of intermittent upper tract obstruction and deteriorating function. The 24-hour urine volume diary is a simple way to assess this.

Salt Depletion

Patients with tubular damage may have a salt-losing tendency. Patients typically have a cool periphery and constricted hand

veins with no peripheral edema. Increasing salt intake can relieve cramps, improve renal function, and reduce hyperuricemia, but at the cost of increasing blood pressure. With patients who are salt depleted, it is important to give sodium chloride because it is the chloride anion that is deficient and responsible for the reduction in circulating volume.

Acidosis

There is often a metabolic acidosis disproportionate to the degree of renal impairment. This is secondary both to a proximal tubular failure of bicarbonate reabsorption and to a distal tubular failure to secrete hydrogen ions. It is our practice to give sufficient sodium bicarbonate to correct the plasma bicarbonate into the normal range.

Bone Disease

In addition to the typical bone disease of progressive CKD, acidosis contributes significantly to osteomalacia. Growing children are particularly vulnerable to osteomalacia, and great care must be taken to correct acidosis and to actively manage bone disease.

Urinary Diversions

Ureterosigmoidostomy

Fortunately, it is now rare to meet a patient who still has a ureterosigmoidostomy, which was widely used as a technique for urinary diversion until the 1970s. The ureters were anastomosed directly into the sigmoid colon with no disruption of bowel continuity. This technique was most commonly used in patients with bladder exstrophy. Although patients start with normal renal function, there is frequently deterioration in function. In one series of 25 patients, significant renal damage occurred in 50%. Stones, infection, and ureteral strictures are common, and patients remain at risk for colonic carcinoma, with a 10% incidence of carcinoma at 20-year follow-up. However, this diversion is probably best known for the hyperchloremic, hypokalemic acidosis that occurs. Once the urine is in contact with the colonic mucosa, the urinary sodium exchanges for potassium and the chloride for bicarbonate, and large quantities of ammonium ions are produced by the action of the fecal bacteria on urinary ammonia. Ammonium ions are absorbed both with chloride and in exchange for sodium. The severe acidosis is a consequence of the ammonium ion retention and stool loss of bicarbonate. Patients are managed with large doses of oral sodium bicarbonate, which is titrated to keep the plasma bicarbonate in the normal range (>22 mmol/l).

Ileal Conduits

Unlike the sigmoidostomy, in which urine enters a reservoir, the ileal conduit is free flowing, with rapid urinary transit and no reservoir. Therefore, metabolic complications are much less common, although again the bowel can exchange sodium and chloride for potassium and bicarbonate.^{45,46} There are a number of other complications of ileal and colonic conduits that can lead to progressive loss of renal function (Fig. 50.24).

Enterocystoplasty and Intestinal Urinary Reservoirs

In a study of 53 patients with bladder exstrophy who were observed for more than 10 years and had serial isotopic GFRs, renal function deteriorated (decrease in GFR of 20% or more)

Long-Term Complications of Urinary Diversion
Pyelonephritis and scarring
Calculi
Obstruction
Strictures
Bladder mucus causing obstruction
Cancer at intestinal–ureteral anastomosis
Hyperchloremic acidosis
Delayed linear growth in children
Effects of intestinal loss from gastrointestinal tract, e.g., vitamin B ₁₂ deficiency
Complications related to abnormal pelvic anatomy, e.g., in pregnancy
Psychological and body image problems

Figure 50.24 Long-term complications of urinary diversion.

in only 10 (20%).³³ Loss of function was caused principally by chronic retention with or without infection in poorly compliant patients who did not catheterize regularly. Patients must also be checked regularly to ensure that anastomotic stenoses and high-pressure reservoirs do not occur. Stones are very common and occur in up to 50% of patients.⁴⁷

END-STAGE RENAL DISEASE AND TRANSPLANTATION

This group of patients presents two important problems at ESRD. First, because of multiple abdominal operations, continuous ambulatory peritoneal dialysis (CAPD) is often impossible, although if there is any doubt, CAPD should be attempted. Second, the bladder and urinary reservoir must be suitable for renal transplantation. If a bladder has just destroyed two perfectly good native kidneys, it is likely to do the same to a transplant kidney. Most patients will be maintained on hemodialysis, but it is frequently difficult to establish a good arteriovenous fistula because of chronic hypovolemia and venoconstriction. Patients on dialysis often continue to pass 1 liter or more of urine per 24 hours, and they also remain at risk for serious UTI and pyelonephritis.

Transplantation

Pretransplantation Assessment

Transplantation into the abnormal lower urinary tract requires careful evaluation and follow-up. Thorough preoperative assessment of bladder function is essential. Patients considered to have normal bladders require at least a postmicturition bladder ultrasound examination and urinary flow rate.

All patients with abnormal bladders or reservoir must have a full videocystometrogram to ensure that the bladder reservoir is large and adequately compliant. If the bladder is small or has not been used for some time, bladder cycling, which involves periodically filling and distending the bladder through a suprapubic catheter, may be required. A study of urodynamics before transplantation indicated that poor bladder function as shown by

small bladder volumes is a predictor of graft loss even in patients with previously normal bladder function.⁴⁸

Intermittent self-catheterization is safe and effective for a patient with a poor flow rate who fails to empty the bladder. This, however, is possible only with a normal urethra and a cooperative patient. When this is not practical, we attempt to establish suprapubic drainage through a continent stoma, for example, a Mitrofanoff stoma (see Fig. 50.23). If a conduit is to be used, then a loopogram and endoscopy must ensure that it is in good condition. We do not remove native kidneys unless they are causing recurrent UTI.

Transplant Outcome

In an 18-year experience, we transplanted 65 patients with abnormal bladders, with a total of 72 renal transplants.⁴⁹ In 52 cases, the ureters were transplanted into unaugmented bladder; in 20 cases, there was some form of augmentation or diversion. Results were compared with 59 transplants in 55 patients who had renal failure from renal dysplasia and whose bladder function was considered to be normal. There was no difference in actuarial graft survival in the two groups at 10 years (abnormal bladders, 66%; normal bladders, 61%), although longer follow-up showed an advantage for normal bladders, with a kidney half-life of 29 to 33 years compared with 15 years for the abnormal bladders.⁴⁹ UTIs were relatively common in all patients but produced problems only in patients with abnormal bladders.

Management

We routinely use double-J ureteral stents at the time of transplant surgery. Adequacy of urinary drainage must be assessed frequently, even when graft function seems to be good. Two months after transplantation, when the ureteral stent has been removed, we perform as a baseline the following tests:

- ⁵¹Cr-EDTA GFR.
- Postmicturition ultrasound of kidney and bladder.
- Dynamic ^{99m}Tc-MAG3 scintigraphy.
- Static ^{99m}Tc-DMSA scintigraphy, as a baseline for renal scarring.

The GFR is repeated at 6 months and then annually. Ultrasound and ^{99m}Tc-MAG3 scintigraphy are repeated at 1 year and then when indicated. The protein-creatinine ratio is measured on a random urine sample at every outpatient visit. If there is renal dysfunction, imaging tests are repeated, and if there is a change from baseline, renal biopsy is performed to exclude an immunologic cause of graft dysfunction. If there is a documented deterioration in renal function in the absence of rejection or calcineurin inhibitor toxicity, the DMSA scan is repeated (to see whether there has been new scarring) and the bladder reassessed urodynamically.⁵⁰

Complications

UTIs must be detected and treated early, and recurrent infections may require long courses of antibiotics or even removal of the native tracts.

In our experience, symptomatic UTIs are common in the first 3 months after transplantation (63%); fever and systemic symptoms occur in 39% with normal bladders and 59% with abnormal bladders. UTI directly contributes to graft loss in patients with abnormal bladders but causes no consequences in those with normal bladders.⁴³ In our practice, prophylactic administration of antibiotics for the first 6 months has halved the subsequent incidence of UTI.

When UTIs recur, a cause must be sought with ultrasound of kidney and bladder. A plain abdominal radiograph is essential to look for stones in native or transplant kidneys and the bladder or urinary diversion. If there is a residual volume after double micturition, the patient must be instructed to perform clean intermittent self-catheterization. With these measures, good results are obtained.

Urinary Tract Infections in Adults

Thomas Hooton

DEFINITION

Urinary tract infection (UTI) in adults can be categorized into six groups: young women with acute uncomplicated cystitis, young women with recurrent cystitis, young women with acute uncomplicated pyelonephritis, adults with acute cystitis and conditions that suggest occult renal or prostatic involvement, complicated UTI, and asymptomatic bacteriuria (Fig. 51.1).¹ A discussion of UTI in pregnancy is provided in Chapter 42 and of vesicoureteral reflux in children in Chapter 61.

Complicated UTI is defined as UTI that increases the risk for serious complications or treatment failure. Patients with various conditions, such as those presented in Figure 51.1, are at increased risk for complicated UTI. Complicated UTIs may require different pretreatment and post-treatment evaluation and type and duration of antimicrobial treatment than for uncomplicated UTI. On occasion, complicated UTIs are diagnosed only after a patient has a poor response to treatment. The physician often must decide, on the basis of limited clinical information, whether to embark on a more extensive evaluation and treatment course when confronted with a patient with UTI.

EPIDEMIOLOGY

Acute uncomplicated UTIs are extremely common, with several million episodes of acute cystitis and at least 250,000 episodes of acute pyelonephritis occurring annually in the United States. The incidence of cystitis in young sexually active women is about 0.5 per 1 person-year.² Acute uncomplicated cystitis may recur in 27% to 44% of healthy women, even though they have normal urinary tracts.³ The incidence of pyelonephritis in young women is about 3 per 1000 person-years.⁴ The self-reported incidence of symptomatic UTI in postmenopausal women is about 10% per year.⁵ The incidence of symptomatic UTI in adult men younger than 50 years is much lower than in women, ranging from 5 to 8 per 10,000 men annually.

Complicated UTIs encompass an extraordinarily broad range of infectious entities (see Fig. 51.1). Nosocomial UTIs are a common type of complicated UTI and occur in 5% of admissions in the university tertiary care hospital setting; catheter-associated infections account for most of the infections. Catheter-associated bacteriuria is the most common source of gram-negative bacteremia in hospitalized patients.⁶

Asymptomatic bacteriuria is defined as two separate consecutive clean-voided urine specimens both with 10^5 or more colony-forming units (cfu)/ml of the same uropathogen in the absence of symptoms referable to the urinary tract.⁷ Asymptomatic

bacteriuria is found in about 5% of young adult women⁸ but rarely in men younger than 50 years. The prevalence increases up to 16% of ambulatory women and 19% of ambulatory men older than 70 years and up to 50% of elderly women and 40% of elderly men who are institutionalized.⁷ Asymptomatic bacteriuria may be persistent or transient and recurrent, and many patients have had previous symptomatic infection or develop symptomatic UTI soon after having asymptomatic bacteriuria. Asymptomatic bacteriuria is generally benign, although as discussed later, it may lead to serious complications in some clinical settings.

PATHOGENESIS

Uncomplicated Infection

Most uncomplicated UTIs in healthy women result when uropathogens (typically *Escherichia coli*) present in the rectal flora enter the bladder through the urethra after an interim phase of periurethral and distal urethral colonization. In the male, colonizing uropathogens may also come from a sex partner's vagina or rectum. Hematogenous seeding of the urinary tract by potential uropathogens such as *Staphylococcus aureus* is the source of some UTIs, but this is more likely to occur in the setting of persistent blood stream infection or urinary tract obstruction.

Many host behavioral, genetic, and biologic factors predispose young healthy women to uncomplicated UTI (Fig. 51.2).⁹ Risk factors include sexual intercourse, use of spermicide products, and a history of previous recurrent UTI.^{2,10} Nonsecretors of ABO blood group antigens have an increased risk for recurrent cystitis, the P₁ blood group phenotype is a risk factor for recurrent pyelonephritis in women, and mutations in the gene for CXCR1, the interleukin-8 receptor, are more frequent and expression of CXCR1 is lower in children prone to pyelonephritis compared with controls.¹¹ Factors protecting individuals from UTI include the host's immune response; maintenance of normal vaginal flora, which protects against colonization with uropathogens; and removal of bladder bacteriuria by micturition.

Certain strains of *E. coli* have a selective advantage for colonization and infection (see Fig. 51.2).¹² P-fimbriated strains of *E. coli* are associated with acute uncomplicated pyelonephritis, and their adherence properties may stimulate epithelial and other cells to produce proinflammatory factors that stimulate the inflammatory response. Other virulence determinants include adherence factors (types 1, S, and Dr fimbriae), toxins (hemolysin), aerobactin, and serum resistance. Bacterial virulence determinants associated with cystitis and asymptomatic bacteriuria have been less well characterized.

Categories of Urinary Tract Infection in Adults
Acute uncomplicated cystitis in young women
Recurrent acute uncomplicated cystitis in young women
Acute uncomplicated pyelonephritis in young women
Acute uncomplicated cystitis in adults with a following condition suggesting possible occult renal or prostatic involvement but without other known complicating factors: <ul style="list-style-type: none">Male sexElderlyPregnancyDiabetes mellitusRecent urinary tract instrumentationChildhood urinary tract infectionSymptoms for more than 7 days at presentation
Complicated urinary tract infection* <ul style="list-style-type: none">Obstruction or other structural factor: urolithiasis, malignancies, ureteral and urethral strictures, bladder diverticula, renal cysts, fistulas, ileal conduits, and other urinary diversionsFunctional abnormality: neurogenic bladder, vesicoureteral refluxForeign bodies: indwelling catheter, ureteral stent, nephrostomy tubeOther conditions: renal failure, renal transplantation, immunosuppression, multidrug-resistant uropathogens, health care associated (includes hospital-acquired [nosocomial] infection, prostatitis-related infection, upper tract infection in an adult other than a young healthy woman, other functional or anatomic abnormality of the urinary tract
Asymptomatic bacteriuria

Figure 51.1 Categories of urinary tract infection in adults. *This is a selected list of complicating factors. Some factors complicate urinary tract infections through several mechanisms. (Data for complicating factors from reference 1.)

Factors Modulating Risk for Acute Uncomplicated Urinary Tract Infections in Women	
Host Determinants	Uropathogen Determinants
Behavioral: sexual intercourse, use of spermicidal products, recent antimicrobial use, suboptimal voiding habits	<i>Escherichia coli</i> virulence determinants: P, S, Dr, and type I fimbriae; hemolysin; aerobactin; serum resistance
Genetic: innate and adaptive immune response; enhanced epithelial cell adherence, antibacterial factors in urine and bladder mucosa, nonsecretor of ABO blood group antigens, P, blood group phenotype, reduced CXCR1 expression, previous history of recurrent cystitis	
Biologic: estrogen deficiency in postmenopausal women, micturition	

Figure 51.2 Factors modulating risk for acute uncomplicated urinary tract infections in women.

Factors affecting the large difference in UTI prevalence between men and women include the greater distance between the usual source of uropathogens (the anus and the urethral meatus), the drier environment surrounding the male urethra, and the greater length of the male urethra. Risk factors associated with UTIs in healthy men include intercourse with an infected female partner, anal intercourse, and lack of circumcision, although these factors are often not present in men with UTI. Most uropathogenic strains infecting young men are highly virulent, suggesting that the urinary tract in healthy men is relatively resistant to infection.

Complicated Infection

The initial steps leading to uncomplicated UTI discussed earlier probably also occur in most individuals who develop a complicated UTI. Factors that predispose individuals to complicated UTI generally do so by causing obstruction or stasis of urine flow, facilitating entry of uropathogens into the urinary tract by bypassing normal host defense mechanisms, providing a nidus for infection that is not readily treatable with antimicrobials, or compromising the host immune system (see Fig. 51.1).¹ UTIs are more likely to become complicated in the setting of impaired host defense, as occurs with indwelling catheter use, vesicoureteral reflux, obstruction, neutropenia, and immune deficiencies. Diabetes mellitus is associated with several syndromes of complicated UTI, including renal and perirenal abscess, emphysematous pyelonephritis and cystitis, papillary necrosis, and xanthogranulomatous pyelonephritis.¹³ Uropathogen virulence determinants are less important in the pathogenesis of complicated UTIs compared with uncomplicated UTIs. However, infection with multidrug-resistant uropathogens is more likely with complicated UTI.

ETIOLOGIC AGENTS

Uncomplicated upper and lower UTI is most commonly due to *E. coli* (present in 70% to 95%) and *Staphylococcus saprophyticus* (present in 5% to more than 20%) (Fig. 51.3). *S. saprophyticus* only rarely causes acute pyelonephritis.¹⁴ Less common causes of uncomplicated UTI include other Enterobacteriaceae, such as *Proteus mirabilis* or *Klebsiella* species; enterococci; group B streptococci; and rarely *Pseudomonas aeruginosa*, *Citrobacter* species, or other uropathogens.

A broader range of bacteria can cause complicated UTI, and many are resistant to broad-spectrum antimicrobial agents. Although *E. coli* is the most common, *Citrobacter* species, *Enterobacter* species, *P. aeruginosa*, enterococci, and *S. aureus* account for

Bacterial Etiology of Urinary Tract Infections		
Organisms	Urinary Tract Infection (%)	
	Uncomplicated	Complicated
Gram-negative organisms		
<i>Escherichia coli</i>	70–95	21–54
<i>Proteus mirabilis</i>	1–2	1–10
<i>Klebsiella</i> species	1–2	2–17
<i>Citrobacter</i> species	<1	5
<i>Enterobacter</i> species	<1	2–10
<i>Pseudomonas aeruginosa</i>	<1	2–19
Other	<1	6–20
Gram-positive organisms		
Coagulase-negative staphylococci (<i>S. saprophyticus</i>)	5–20 or more	1–4
Enterococci	1–2	1–23
Group B streptococci	<1	1–4
<i>Staphylococcus aureus</i>	<1	1–2
Other	<1	2

Figure 51.3 Bacterial etiology of urinary tract infections. (Data for complicated infections from reference 1.)

a relatively higher proportion of cases compared with uncomplicated UTIs (see Fig. 51.3).¹ The proportion of infections caused by fungi, especially *Candida* species, is increasing (see Chapter 53). Patients with chronic conditions, such as spinal cord injury and neurogenic bladder, are more likely to have polymicrobial (multiorganism) and multidrug-resistant infections.

CLINICAL SYNDROMES

Acute Uncomplicated Cystitis in Young Women

Women with acute uncomplicated cystitis generally present with acute onset of dysuria, frequency, urgency, or suprapubic pain. Acute dysuria in a young sexually active woman is usually caused by acute cystitis; acute urethritis from *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, or herpes simplex virus infections; or vaginitis caused by *Candida* species or *Trichomonas vaginalis*.⁶ These three entities can usually be distinguished by the history, physical examination, and simple laboratory tests. Pyuria is present in almost all women with acute cystitis as well as in most women with urethritis caused by *N. gonorrhoeae* or *C. trachomatis*, and its absence strongly suggests an alternative diagnosis. Hematuria (microscopic or gross) is common in women with UTI but not in women with urethritis or vaginitis.

Definitive diagnosis of UTI requires the presence of significant bacteriuria, the traditional standard for which is 10^5 or more uropathogens per milliliter of voided midstream urine. Studies have shown, however, that up to one third of patients with cystitis have lower colony counts, which are missed with use of the traditional definition. The Infectious Diseases Society of America consensus definition of cystitis is 10^3 cfu/ml or more (sensitivity, 80%; specificity, 90%).¹⁵ Urine cultures are generally not in women with uncomplicated cystitis because the causative organisms are predictable and the culture results become available only after therapeutic decisions have been made.

E. coli in uncomplicated UTI is often resistant to sulfonamides and amoxicillin, and increasing resistance is also being observed for trimethoprim and trimethoprim-sulfamethoxazole (cotrimoxazole) among outpatient urinary strains in the United States and Europe.^{16,17} Many drug-resistant *E. coli* are clonal and have been hypothesized to enter new environments by contaminated products ingested by community residents.¹⁸ The prevalence of

E. coli resistance to nitrofurantoin is generally less than 5%, although nitrofurantoin is inactive against *Proteus* species and some *Enterobacter* and *Klebsiella* strains. Fluoroquinolones remain active against most *E. coli* strains causing uncomplicated cystitis, although resistance is increasing in certain areas of the world.^{16,17}

Three-day regimens are recommended for the treatment of acute uncomplicated cystitis because of comparable efficacy, better compliance, lower cost, and lower frequency of adverse reactions than with longer regimens. Single-dose regimens, although highly effective in most women (especially trimethoprim-sulfamethoxazole and fluoroquinolones), are less effective than longer regimens.¹⁹ Higher cure rates have been observed with trimethoprim-sulfamethoxazole and fluoroquinolones than with β -lactams regardless of the site of infection and duration of treatment.

Optimal management of acute uncomplicated cystitis is summarized in Figures 51.4 and 51.5. Trimethoprim or trimethoprim-sulfamethoxazole in a 3-day oral regimen should be considered the first-line agents for uncomplicated cystitis in women who can tolerate them and in areas where resistance is infrequent.²⁰ Nitrofurantoin is equally effective in a 5-day regimen, and should also be considered a first-line agent for uncomplicated cystitis. Fluoroquinolones (3-day duration) are highly effective in the treatment of cystitis, but resistance is increasing worldwide, even among uropathogens causing uncomplicated cystitis, and many experts in UTI now recommend that they be considered as second-line therapy for uncomplicated cystitis to help preserve their usefulness in the treatment of other infections. In this regard, fosfomycin and pivmecillinam should be considered as fluoroquinolone-sparing antimicrobials in patients with uncomplicated cystitis, even though they may be less effective than other first-line agents.²¹ Broad-spectrum oral cephalosporins (such as cefixime, cefpodoxime, cefprozil, and cefaclor) demonstrate in vitro activity against most uropathogens causing uncomplicated cystitis, but clinical data are sparse. A recent trial demonstrated that a 3-day regimen of amoxicillin-clavulanate is significantly inferior to a 3-day regimen of ciprofloxacin, even when the uropathogens were susceptible to the drugs with which they were treated.²² β -Lactam antibiotics have generally been inferior to trimethoprim-sulfamethoxazole or fluoroquinolones in regimens of the same duration.²⁰

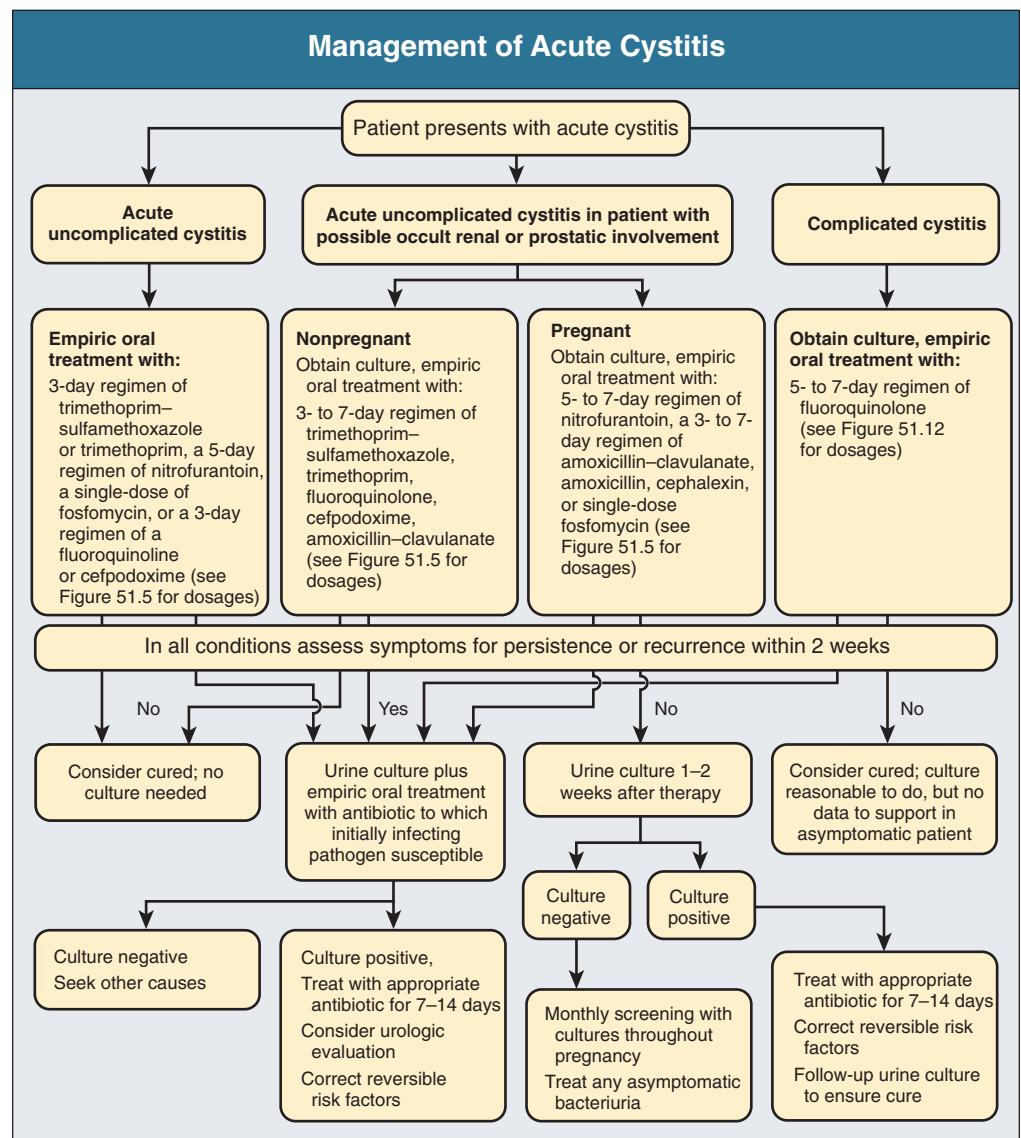

Routine post-treatment cultures in women are not indicated unless the patient is symptomatic. If the patient remains symptomatic and has documented persistent infection, a longer course of therapy based on sensitivities, usually with a fluoroquinolone, should be used. The benefit of detecting and treating asymptomatic bacteriuria in healthy women has been demonstrated only in pregnancy and before urologic instrumentation or surgery.^{7,23}

Recurrent Acute Uncomplicated Cystitis in Women

Most recurrent cystitis in healthy women is due to repeated infection, which in many cases is caused by persistence of the initially infecting strain in the fecal flora.²⁴ Experimental studies in mice also suggest that some same-strain recurrent UTIs may be caused by a latent reservoir of uropathogens in the bladder epithelium that persist after the initial UTI.^{24,25}

Women with recurrent cystitis may benefit from behavioral modification (Fig. 51.6), such as increasing fluid intake and ensuring postcoital micturition, although the benefit of these practices has not been proved. Small studies suggest that ingestion of cranberry products has preventive properties, and *in vitro* studies have shown that cranberry juice blocks adherence of

Figure 51.4 Algorithm for management of acute cystitis.

E. coli to epithelial cells. Clinical trials are currently in progress, but it is reasonable to recommend daily cranberry products to women with frequent recurrences of UTI. Women who do not wish to try or who obtain no benefit from the preceding approaches should be offered antimicrobial prophylaxis.

Antimicrobial prophylaxis is effective in preventing recurrent UTI in women (Fig. 51.7; see also Fig. 51.6). Prophylaxis should be considered for women who experience three or more infections during a 12-month period or whenever the woman thinks that her life is being adversely affected by frequent recurrences. Several approaches have been used, including continuous prophylaxis, postcoital prophylaxis, and intermittent self-treatment (which is really an early treatment method). In postmenopausal women with recurrent UTI, intravaginal estriol is effective, presumably by normalizing the vaginal flora, which reduces the risk for coliform colonization of the vagina.²⁴ This approach offers an alternative to antimicrobial strategies (see Fig. 51.6).

Acute Uncomplicated Pyelonephritis in Women

Acute pyelonephritis is suggested by fever (temperature $\geq 38.5^{\circ}\text{C}$), chills, flank pain, nausea and vomiting, and costovertebral angle

tenderness. Cystitis symptoms are variably present. Symptoms may vary from a mild illness to a sepsis syndrome with or without shock and renal failure. Pyuria is almost always present, but leukocyte casts, specific for UTI, are infrequently seen. Gram stain of the urine sediment may aid in differentiating gram-positive and gram-negative infections, which can influence empiric therapy. A urine culture, which should be performed in all women with acute pyelonephritis, will have 10^4 cfu/ml or more uropathogens in up to 95% of patients.¹⁵

On pathologic examination, the kidney shows a focal inflammatory reaction with neutrophil and monocyte infiltrates, tubular damage, and interstitial edema (Fig. 51.8). Although imaging studies are generally not performed, the infected kidney is often enlarged, and contrast-enhanced computed tomography (CT) shows decreased opacification of the affected parenchyma, typically in patchy, wedge-shaped, or linear patterns (Fig. 51.9).

The availability of effective oral antimicrobials, especially the fluoroquinolones, allows initial oral therapy in appropriate patients or, in those requiring parenteral therapy, the timely conversion from intravenous to oral therapy and reduced need for hospitalization. Indications for admission to the hospital include inability to maintain oral hydration or to take

Oral Regimens for Acute Uncomplicated Cystitis			
Drug	Dose (mg)	Interval	Comment
Trimethoprim-sulfamethoxazole	160/800	q 12 h	If used in pregnancy (not approved use), avoid in first trimester.
Trimethoprim	100	q 12 h	If used in pregnancy (not approved use), avoid in first trimester.
Nitrofurantoin Monohydrate/macrocystals	100	q 12 h	Less active against <i>Proteus</i> species
Macrocrystals	50	q 6 h	
Cefpodoxime proxetil	100	q 12 h	Comparable to Tmp-smx in efficacy, but data sparse
Fosfomycin	3000	Single dose	Less effective vs. fluoroquinolone or trimethoprim-sulfamethoxazole
Amoxicillin-clavulanate	500/125	q 12 h	Inferior to ciprofloxacin in 3-day regimen
Amoxicillin	500	q 12 h	Used only when causative pathogen is known to be susceptible or for empiric treatment of mild cystitis in pregnancy
Fluoroquinolones			Avoid fluoroquinolones if possible in pregnancy, nursing mothers, or persons <18 years old. Although highly effective, should be considered second line treatment to preserve its usefulness for other infections
Ciprofloxacin	100–250	q 12 h	
Ciprofloxacin extended release	500	q 24 h	
Levofloxacin	250	q 24 h	
Ofloxacin	200	q 12 h	

Figure 51.5 Oral antimicrobial agents for acute uncomplicated cystitis or cystitis in patients with possible occult renal or prostatic involvement. Duration of therapy depends on the clinical setting (see text and Fig. 51.4).

medications; uncertain social situation or concern about compliance; uncertainty about the diagnosis; and severe illness with high fevers, severe pain, and marked debility. Outpatient therapy is safe and effective for selected patients who can be stabilized with parenteral fluids and antibiotics in an urgent care facility and sent home with oral antibiotics under close supervision. In one population-based study of acute pyelonephritis in adult women, only 7% were hospitalized.⁴

The management strategy for acute uncomplicated pyelonephritis is shown in Figure 51.10. There are many effective parenteral (Fig. 51.11) and oral (Fig. 51.12) regimens for acute uncomplicated pyelonephritis. In the outpatient setting, an oral fluoroquinolone should be used for initial empiric treatment of infection caused by gram-negative bacilli.²⁰ Trimethoprim-sulfamethoxazole or other agents can be used if the infecting strain is known to be susceptible. If enterococci are suspected from the Gram stain, amoxicillin should be added to the treatment regimen until the causative organism is identified. Second- and third-generation cephalosporins also appear effective, although published data are sparse. Neither nitrofurantoin nor fosfomycin is approved or recommended for the treatment of pyelonephritis.

For hospitalized patients, ceftriaxone is an effective and inexpensive agent if the Gram stain is not suggestive of gram-positive bacterial infection. If enterococci are suspected on the basis of a stain showing gram-positive bacteria, ampicillin plus gentamicin, ampicillin-sulbactam, and piperacillin-tazobactam are reasonable broad-spectrum empiric choices. Trimethoprim-sulfamethoxazole should not be used alone for empiric therapy for pyelonephritis in areas with a high prevalence of resistance to this combination. Patients with acute uncomplicated pyelonephritis can often be switched to oral therapy after 24 to 48 hours,

although longer intervals of parenteral therapy are occasionally indicated in patients whose symptoms and signs do not improve rapidly (such as those with continued high fever, severe flank pain, or persistent nausea and vomiting).

Treatment of acute uncomplicated pyelonephritis can be limited to 7 days for mildly to moderately ill patients who have a rapid response with resolution of fever and symptoms soon after initiation of treatment. However, β -lactam regimens shorter than 14 days have been associated with unacceptably high failure rates in some studies.²⁰ One study demonstrated superiority of a 7-day ciprofloxacin regimen over a 14-day trimethoprim-sulfamethoxazole regimen, with the difference accounted for entirely by the higher rate of resistance of the uropathogens to trimethoprim-sulfamethoxazole.¹⁴

Routine post-treatment urine cultures in asymptomatic patients are not cost-effective, but cultures should be performed if symptoms persist or recur. Recurrent infections are treated with a 7- to 14-day course of an antibiotic to which the organism is susceptible. Symptomatic patients who have persistent infection with the same strain as the initial infecting strain warrant 10 to 14 days of therapy, or even longer in some cases, and complicating factors should be looked for and corrected if found.

Acute Cystitis in Healthy Adults with Possible Occult Renal or Prostatic Involvement

Acute cystitis in healthy individuals other than young women are more likely to involve occult renal or prostatic infection (see Fig. 51.1) and may respond poorly to short-course therapy. We lack noninvasive tools to localize infections to the kidney or prostate, so our estimation of risk in a given patient is imprecise. Some patients, such as those with diabetes or pregnancy, warrant

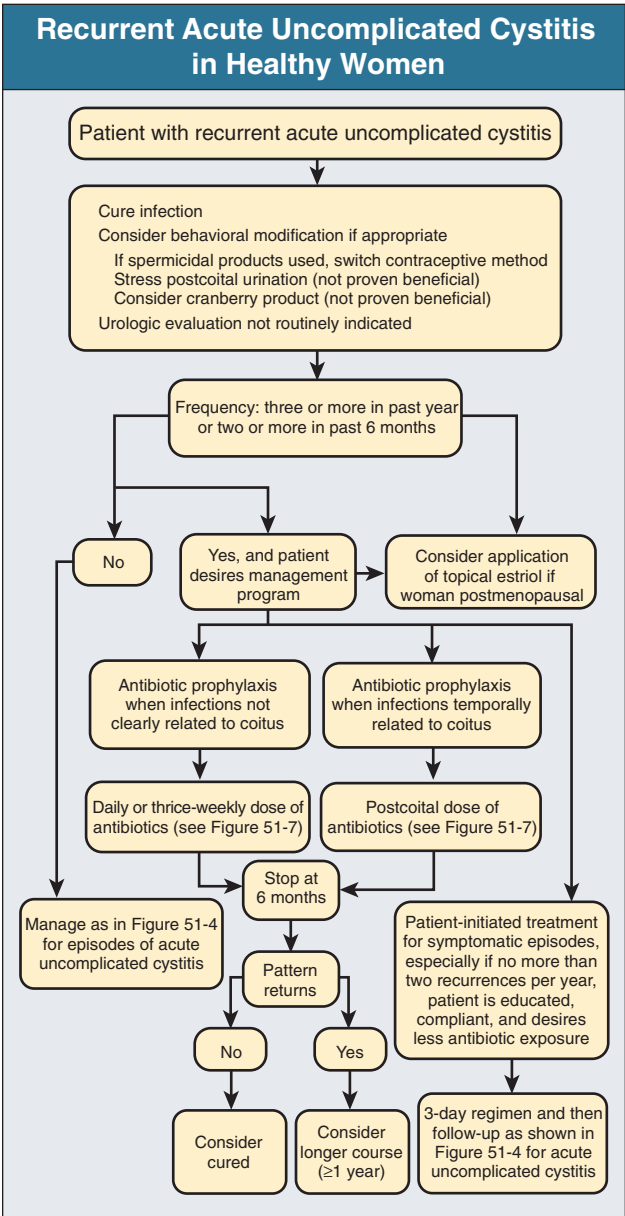

Figure 51.6 Management strategies for recurrent acute uncomplicated cystitis.

special attention because of the serious complications that can occur if treatment is inadequate. Symptoms, signs, and laboratory findings in this group are the same as those in uncomplicated cystitis. Urethritis must be excluded in dysuric sexually active men by a urethral Gram stain or a first-voided urine specimen wet mount evaluation for urethral leukocytosis.

A urine culture specimen should be obtained routinely in patients before treatment (see Fig. 51.4). Empiric treatment is similar to that used for uncomplicated cystitis in women. Nitrofurantoin treatment should be avoided except for cystitis in pregnancy, in which duration of treatment is 5 to 7 days, depending on the severity of symptoms.

The need for post-treatment culture is less certain, except in pregnant women (see Fig. 51.4). In men, early recurrence of UTI with the same species suggests a prostatic source of infection and warrants a 4- to 6-week regimen of either a fluoroquinolone (preferable) or trimethoprim-sulfamethoxazole.

Prophylaxis for Recurrent Acute Uncomplicated Cystitis		
Drug	Dose (mg)	Frequency
Continuous prophylaxis		
Trimethoprim-sulfamethoxazole	40/200	Daily
Trimethoprim-sulfamethoxazole	40/200	Thrice weekly
Trimethoprim	100	Daily
Nitrofurantoin	50 or 100	Daily
Cefaclor	250	Daily
Cefalexin (cephalexin)	125 or 250	Daily
Norfloxacin*	200	Other fluoroquinolones are likely to be as effective*
Postcoital prophylaxis		
Trimethoprim-sulfamethoxazole	40/200	Single dose
Trimethoprim-sulfamethoxazole	80/400	Single dose
Nitrofurantoin	50 or 100	Single dose
Cefalexin	250	Single dose
Ciprofloxacin*	125	Single dose
Norfloxacin*	200	Single dose
Ofloxacin*	100	Single dose

Figure 51.7 Antimicrobial prophylaxis regimens for women with recurrent acute uncomplicated cystitis. See text and Figure 51.6 for management strategy. *Women should be cautioned about pregnancy when fluoroquinolones are being used.

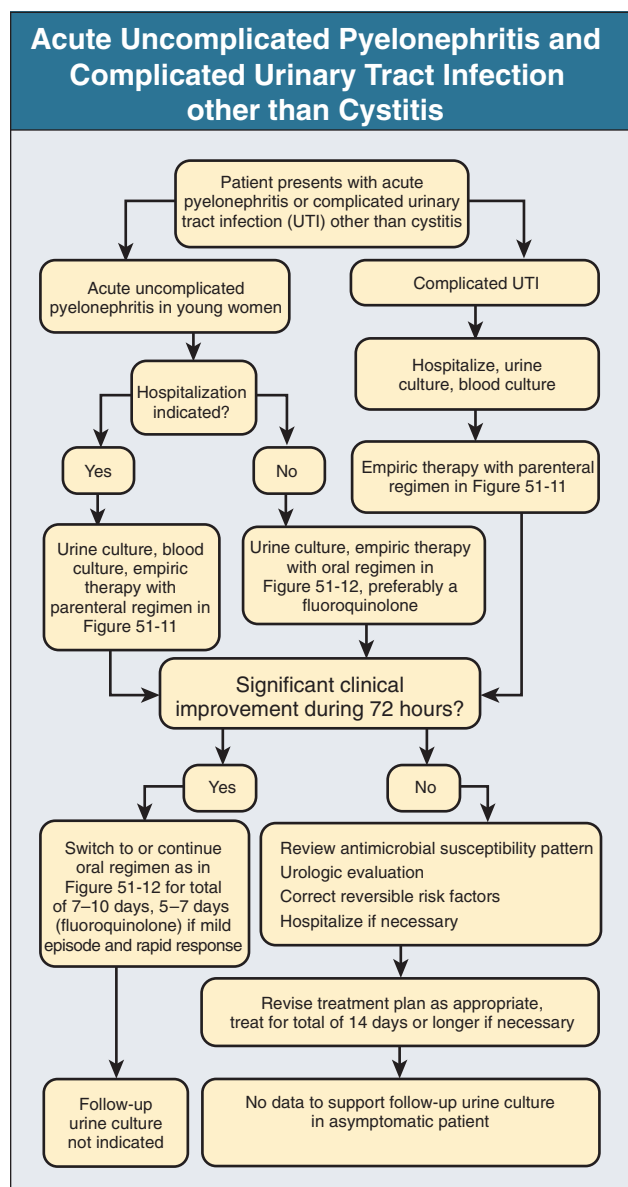

Figure 51.10 Management algorithm for acute uncomplicated pyelonephritis and complicated urinary tract infection other than cystitis.

Complicated Infections

Complicated UTI may present with classic signs of cystitis and pyelonephritis but may also be associated with vague or nonspecific symptoms, such as fatigue, irritability, nausea, headache, and abdominal or back pain. Signs and symptoms may exist for weeks to months before diagnosis. Complicated UTI, like uncomplicated UTI, is generally associated with pyuria and bacteriuria, although these may be absent if the infection does not communicate with the collecting system.

Urine culture should always be performed in patients with suspected complicated UTI. The Infectious Diseases Society of America consensus definition of complicated UTI is 10^5 cfu/ml or more in women and 10^4 cfu/ml or more in men,¹⁵ but lower counts in symptomatic persons, as has been demonstrated in patients with uncomplicated UTI, may well represent significant bacteriuria. This is especially true when the specimen is collected from a urinary catheter. Thus, it is reasonable to use a colony

Parenteral Regimens for Acute Uncomplicated Pyelonephritis and Complicated Urinary Tract Infection

Drug	Dose (mg)	Interval
Ceftriaxone	1000–2000	q 24 h
Cefepime	1000–2000	q 12 h
Fluoroquinolones [†]		
Ciprofloxacin	200–400	q 12 h
Levofloxacin	250–750	q 24 h
Gentamicin (± ampicillin)	3–5 mg/kg body weight 1 mg/kg body weight	q 24 h q 8 h
Ampicillin (+ gentamicin)	1000	q 6 h
Trimethoprim-sulfamethoxazole [†]	160/800	q 12 h
Aztreonam	1000	q 8–12 h
Ampicillin-sulbactam	1500	q 6 h
Ticarcillin-clavulanate	3200	q 8 h
Piperacillin-tazobactam	3375	q 6–8 h
Imipenem-cilastatin	250–500	q 6–8 h
Ertapenem	1000	q 24 h
Vancomycin [§]	1000	q 12 h

Figure 51.11 Parenteral regimens for acute uncomplicated pyelonephritis and complicated urinary tract infection. Duration depends on clinical setting (see text and Fig. 51.10). [†]Avoid, if possible, in pregnancy. [§]Recommended if methicillin-resistant *S. aureus* (MRSA) is suspected or known.

count threshold of 10^3 cfu/ml or more to diagnose complicated UTI.

The wide variety of underlying conditions (see Fig. 51.1), diverse bacterial agents (see Fig. 51.3), and paucity of controlled clinical trials make generalizations about antimicrobial therapy difficult. The management strategy for complicated cystitis is shown in Figure 51.4 and that for complicated infections other than cystitis in Figure 51.10.

Attempts to correct any underlying anatomic, functional, or metabolic defect must be made as antibiotics alone may not be successful.¹ For empiric therapy in patients with mild to moderate illness who can be treated with oral medication, the fluoroquinolones provide the broadest spectrum of antimicrobial activity, cover most expected pathogens, and achieve high levels in the urine and urinary tract tissue. Exceptions are trovafloxacin and moxifloxacin, which, in contrast to other fluoroquinolones such as ciprofloxacin and levofloxacin, may not achieve sufficient concentrations in urine to be effective for complicated UTI. If the infecting pathogen is known to be susceptible, trimethoprim-sulfamethoxazole or other agents are reasonable therapeutic choices.

For initial treatment in more seriously ill, hospitalized patients, several parenteral antimicrobial agents are available (see Fig. 51.11). The broader spectrum agents shown in Figure 51.11 are preferable for health care–associated infections. In contrast to uncomplicated UTI, *S. aureus* is more common in complicated UTIs, and if it is suspected, the therapeutic regimen should have activity against this pathogen. Studies show that a high proportion of *S. aureus* isolates, even in the community are methicillin-resistant (MRSA), so vancomycin should be included

Oral Regimens for Acute Uncomplicated Pyelonephritis and Complicated Urinary Tract Infection			
Drug	Dose (mg)	Interval	Comment
Fluoroquinolones			
Ciprofloxacin	500	q 12 h	Preferred for empiric treatment; avoid if possible in pregnancy, nursing mothers, or persons <18 years old
Ciprofloxacin extended release	1000	q 24 h	
Levofloxacin	250–750	q 24 h	
Trimethoprim-sulfamethoxazole	160/800	q 12 h	Use only when the causative pathogen is known to be susceptible If used in pregnancy (not approved use), avoid in first trimester
Cefpodoxime proxetil	200	q 12 h	Data are sparse
Amoxicillin	500	q 8 h	Use only when the causative pathogen is known to be susceptible or in addition to a broad-spectrum agent when empiric coverage against enterococci is desirable

Figure 51.12 Oral regimens for acute uncomplicated pyelonephritis and complicated urinary tract infection. Duration depends on clinical setting (see text and Fig. 51.10).

in the empiric treatment regimen if *S. aureus* is suspected. Potential concerns that must be considered in the management of complicated UTI include the increasing prevalence of resistance to fluoroquinolones in institutional settings and the frequency of enterococcal infections.

The antimicrobial regimen can be modified when the infecting strain has been identified and antimicrobial susceptibilities are known. Patients who are given parenteral therapy can be switched to oral treatment after clinical improvement. Few studies have been performed that evaluate duration of treatment in populations with complicated UTIs. However, it is desirable to limit the duration of treatment, especially for milder infections, to reduce the selection pressure for drug-resistant flora. In one study, clinical and microbiologic success rates after treatment were almost identical in patients with acute pyelonephritis or complicated UTI treated with a 5-day course of levofloxacin or a 10-day course of ciprofloxacin.²⁷ These data suggest that a 7- to 10-day regimen is reasonable for most patients with complicated UTI, depending on their clinical response; shorter regimens, such as a 5-day regimen of a urinary fluoroquinolone, are likely to be sufficient in those patients who are less severely ill, are infected with uropathogens susceptible to the antibiotic used, and have a rapid response to treatment. At least 10 to 14 days of therapy is recommended in those patients who have a delayed response.

Catheter-Associated Infections

Approximately 15% to 25% of patients in general hospitals have a catheter inserted at some time during their stay, and approximately 5% to 10% of long-term care facility residents are managed with urethral catheterization, in some cases for years. The incidence of bacteriuria associated with indwelling catheterization is 3% to 10% per day of catheterization, and the duration

of catheterization is the most important risk factor for the development of catheter-associated bacteriuria.

Catheter-associated bacteriuria is the most common source of gram-negative bacteremia in hospitalized patients. Complications of long-term catheterization (>30 days) include almost universal bacteriuria, often with multiple antibiotic-resistant flora, and (in addition to cystitis, pyelonephritis, and bacteremia as seen with short-term catheterization) frequent febrile episodes, catheter obstruction, stone formation associated with urease-producing uropathogens, and local genitourinary infections. Other rare complications include fistula formation and bladder cancer. An increase in mortality risk has been reported with catheter-associated bacteriuria, but it is difficult to distinguish the role of the catheter because most deaths occur in patients who have severe underlying disease.

Most episodes of catheter-associated bacteriuria are asymptomatic and do not require routine screening or treatment because treatment does not reduce the complications of bacteriuria and can lead to antimicrobial resistance.⁷ Symptomatic infections, often caused by multiple multidrug-resistant uropathogens, warrant broad-spectrum therapy as described previously. In a symptomatic catheterized patient, a urine culture specimen should be obtained from a freshly placed catheter if the catheter has been in place for a few days because the catheter biofilm may result in spurious culture results. Moreover, clinical outcomes are improved if the catheter is replaced at the time of antimicrobial therapy.²⁸

Preventive measures are indicated to reduce the morbidity, mortality, and costs of catheter-associated infection. Effective strategies include avoidance of a catheter when possible and, when the catheter is necessary, sterile insertion, prompt removal, and strict adherence to a closed collecting system.^{6,29} Meta-analyses have shown that rates of catheter-associated bacteriuria, at least in patients catheterized for less than 2 weeks, are higher among patients with an indwelling urethral catheter compared with those on intermittent or suprapubic catheterization.³⁰ Likewise, condom catheterization is preferable to indwelling urethral catheterization in appropriately selected men.³¹ Even though they are highly effective in reducing catheter-associated UTI rates, prophylactic systemic antimicrobial agents are generally not recommended for routine use because of concerns about selection for antimicrobial resistance. Antimicrobial-coated catheters appear to be effective in reducing catheter-associated bacteriuria in patients catheterized for less than 2 weeks, but they have not been shown to be effective in reducing symptomatic infection.

Spinal Cord Injury

Spinal cord injury alters the dynamics of voiding and often requires the use of bladder drainage with catheters. The diagnosis of UTI in patients with spinal cord injuries is often problematic and is based on the combination of symptoms and signs (which are often nonspecific), pyuria, and significant bacteriuria; uropathogens are often present in quantities of 10⁵ cfu/ml or more. Fluoroquinolones are the empiric oral agents of choice in patients with mild to moderate infection, although many uropathogens, even in the outpatient setting, are resistant to this class of antibiotic, and parenteral antibiotics may be needed.

Treatment of asymptomatic bacteriuria in patients with spinal cord injuries is not of proven benefit and increases the risk for infection with antimicrobial-resistant uropathogens.^{7,32} Likewise, antibiotic prophylaxis is generally not recommended, although it may be considered for selected outpatients with

frequent symptomatic UTIs for whom there are no correctible risk factors.

Prostatitis

Prostatitis occurs in about 2% to 10% of men during their lifetime, but it is caused by acute or chronic bacterial infection in a minority.³³ The current National Institutes of Health classification system categorizes prostatitis within a complex series of syndromes that vary widely in clinical presentation and response to treatment. The most common organisms causing bacterial prostatitis are gram-negative bacilli, including *E. coli*, *Proteus* species, *Klebsiella* species, *P. aeruginosa*, and, less commonly, enterococci and *S. aureus*. The pathogenesis of prostatitis is believed to be related to reflux of infected urine from the urethra into the prostatic ducts. Prostatic calculi, commonly found in adult men, may provide a nidus for bacteria and protection from antibacterial agents.

Acute bacterial prostatitis is rare. Patients present with dysuria, frequency, urgency, obstructive voiding symptoms, fever, chills, and myalgias. The prostate is tender and swollen. Prostatic massage, as a diagnostic test, is contraindicated in men in whom the diagnosis of acute prostatitis is being considered because of the risk for precipitating bacteremia. The patient will usually have pyuria and a positive urine culture. Patients who are severely ill require hospitalization and parenteral antibiotics, but many patients can be treated in the outpatient setting with oral fluoroquinolones. The duration of treatment is recommended to be at least 30 days.³³ Abscess formation may rarely occur.

Chronic bacterial prostatitis is characterized by recurrent UTIs with the same uropathogen with intervening asymptomatic periods. The prostate typically is normal to palpation during asymptomatic periods. Chronic bacterial prostatitis is characterized microscopically by the presence of 10 or more leukocytes per high-power field in expressed prostatic secretions or post-massage voided urine in the absence of significant pyuria in first-voided and midstream urine specimens and a uropathogen colony count that is at least 10-fold higher in the expressed prostatic secretions or postmassage voided urine compared with the first-voided midstream urine. In addition, macrophage-laden fat droplets (oval fat bodies) are usually prominent in the prostatic secretions. These tests, however, are infrequently performed by urologists. Cure rates, which historically have been low, are 60% to 80% with the fluoroquinolones, which are the antibiotics of choice. The optimal duration of treatment is unknown, but most authorities recommend at least 1 to 3 months. Some patients require long-term, low-dose suppressive therapy to prevent symptomatic UTIs. Surgical intervention is only rarely considered and is associated with high morbidity.

Renal Abscess

Renal cortical and corticomedullary abscesses and perirenal abscesses occur in 1 to 10 per 10,000 hospital admissions.³⁴ Patients usually present with fever, chills, back or abdominal pain, and costovertebral angle tenderness but may have no urinary symptoms or findings if the abscess does not communicate with the collecting system, as is often the case with a cortical abscess. Bacteremia may be primary (cortical abscess) or secondary (corticomedullary or perirenal). The clinical presentation may be insidious and nonspecific, especially with perirenal abscess, and the diagnosis may not be made until admission to a hospital or at autopsy. CT is recommended to establish the diagnosis and location of a renal or perirenal abscess (Fig. 51.13). Empiric antibiotic therapy should be broad and cover *S. aureus*

Figure 51.13 Renal abscess. Contrast-enhanced CT scan shows an abscess in the medulla of the kidney (arrowhead) with penetration and extension into the perinephric space (arrows). (Courtesy L. Towner.)

and other uropathogens causing complicated UTI (see Figs. 51.10 and 51.11) and modified once urine culture results are known.

A renal cortical abscess (renal carbuncle) is usually caused by *S. aureus*, which reaches the kidney by hematogenous spread. Treatment with antibiotics is usually effective, and drainage is not required unless the patient is slow to respond. A renal corticomedullary abscess, in contrast, usually results from ascending UTI in association with an underlying urinary tract abnormality, such as obstructive uropathy or vesicoureteral reflux, and is usually caused by common uropathogenic species such as *E. coli* and other coliforms. Such abscesses may extend deep into the renal parenchyma, perforate the renal capsule, and form a perirenal abscess. Treatment with antimicrobial agents without drainage may be effective if the abscess is small and if the underlying urinary tract abnormality can be corrected. Aspiration of the abscess may be necessary in some patients, and nephrectomy may occasionally be required in patients with diffuse renal involvement or with severe sepsis. Perirenal abscesses usually occur in the setting of obstruction or other complicating factors (see Fig. 51.1) and result from ruptured intrarenal abscesses, hematogenous spread, or spread from a contiguous infection. Causative uropathogens are those commonly found in complicated UTIs (see Fig. 51.3), including *S. aureus* and enterococci; polymicrobial infections are common. Anaerobes or *Mycobacterium tuberculosis* may be causative. A previously high mortality rate has been lowered with earlier diagnosis and therapy. In contrast to the other types of abscess, drainage of pus is the cornerstone of therapy, and nephrectomy is sometimes indicated.

Papillary Necrosis

More than half of those who develop papillary necrosis have diabetes, almost always in conjunction with a UTI, but the condition also complicates sickle cell disease, analgesic abuse, and obstruction. Renal papillae are vulnerable to ischemia because of the sluggish blood flow in the vasa recta, and relatively modest ischemic insults may cause papillary necrosis. The clinical features are those typical of pyelonephritis. In addition, passage of sloughed papillae into the ureter may cause renal colic, renal insufficiency or failure, or obstruction with severe urosepsis. Papillary necrosis in the setting of pyelonephritis is associated with pyuria and a positive urine culture. Causative uropathogens

are those typical of complicated UTI. Spiral CT is the preferred diagnostic procedure. Radiologic findings include an irregular papillary tip; dilated calyceal fornix; extension of contrast material into the parenchyma; and a separated crescent-shaped papilla surrounded by contrast material, called the ring sign. Broad-spectrum antibiotics are indicated. Papillae obstructing the ureter may require removal with a cystoscopic ureteral basket or relief of obstruction by insertion of a ureteral stent.

Emphysematous Pyelonephritis

Emphysematous pyelonephritis is a fulminant, necrotizing, life-threatening variant of acute pyelonephritis caused by gas-forming organisms, including *E. coli*, *K. pneumoniae*, *P. aeruginosa*, and *Proteus mirabilis*.³⁵ Up to 90% of cases occur in diabetic patients, and obstruction may be present. Symptoms are suggestive of pyelonephritis, and there may be a flank mass. Dehydration and ketoacidosis are common. Pyuria and a positive urine culture are usually present. Gas is usually detected by a plain abdominal radiograph or ultrasound (Fig. 51.14). CT is the diagnostic modality of choice, however, because it can better localize the gas than ultrasound can. Accurate localization of gas is important because gas may also form in an infected obstructed collecting

Figure 51.14 Emphysematous pyelonephritis. A plain radiograph in this febrile diabetic subject revealed diffuse gas formation throughout both kidneys (outlined by arrows) and gas dissecting in the left retroperitoneal space (arrowheads). (Courtesy W. Bush, University of Washington, Seattle, Washington, USA.)

system or renal abscess; although serious, these conditions do not carry the same grave prognosis and are managed differently. Parenteral broad-spectrum antibiotics and percutaneous catheter drainage with relief of obstruction may be adequate for those less severely ill, but nephrectomy is warranted for those who are more severely ill and those less severely ill who do not respond to the preceding steps. Medical treatment is associated with a mortality rate of 60% to 80%, which is lowered to 20% or less with surgical intervention.

Renal Malacoplakia

Malacoplakia is a chronic granulomatous disorder of unknown etiology involving the genitourinary, gastrointestinal, skin, and pulmonary systems.³⁶ It is characterized by an unusual inflammatory reaction to a variety of infections and is manifested by the accumulation of macrophages containing calcified bacterial debris called Michaelis-Gutmann bodies (Fig. 51.15). The underlying disorder appears to be a monocyte-macrophage bactericidal defect. The diagnosis is made by histologic examination of involved tissue. Genitourinary malacoplakia, most commonly involving the bladder, is usually associated with gram-negative UTI. Patients with renal malacoplakia generally have fever, flank pain, pyuria and hematuria, bacteriuria, and, if both kidneys are involved, impaired renal function. CT scanning usually shows enlarged kidneys with areas of poor enhancement, and the condition may be indistinguishable from other infectious or neoplastic lesions. On occasion, the malacoplakia may extend through the renal capsule into the perinephric space, simulating a renal carcinoma (see Fig. 51.15). Treatment consists of therapy with a broad spectrum antimicrobial; correction of any underlying complicating conditions if possible, and improvement of renal function. Nephrectomy is recommended for advanced unilateral disease. When the disease is bilateral or occurs in a transplanted kidney, the prognosis is very poor.

Xanthogranulomatous Pyelonephritis

Xanthogranulomatous pyelonephritis is a poorly understood, uncommon, but severe chronic renal infection associated with obstruction of the urinary tract.³⁴ The renal parenchyma is replaced with a diffuse or segmental cellular infiltrate of foam cells, which are lipid-laden macrophages. The process may also extend beyond the renal capsule to the retroperitoneum. Its pathogenesis appears to be multifactorial, with infection

Figure 51.15 Renal malacoplakia. A, Malacoplakia involving most of the kidney (arrows) with extension through the capsule (asterisks). A small portion of normal kidney is present that is associated with hydronephrosis secondary to obstruction by the malacoplakia. B, The kidney tissue shows many macrophages containing intracytoplasmic inclusions (arrows identify two particularly well demarcated macrophages with Michaelis-Gutmann bodies). (Courtesy L. Truong, Baylor College of Medicine, Houston, Texas, USA and N. Sheerin, Guy's Hospital, London, United Kingdom.)

complicating obstruction and leading to ischemia, tissue destruction, and accumulation of lipid deposits. Patients with xanthogranulomatous pyelonephritis are characteristically middle-aged women and have chronic symptoms such as flank pain, fever, chills, and malaise. Flank tenderness, a palpable mass, and irritative voiding symptoms are common. The urine culture is usually positive with *E. coli*, other gram-negative bacilli, or *S. aureus*. CT generally shows an enlarged nonfunctioning kidney, often the presence of calculi and low-density masses (xanthomatous tissue), and, in some cases, involvement of adjacent structures (Fig. 51.16). It may be difficult to distinguish from neoplastic disease. Broad-spectrum antimicrobials are indicated, but total or partial nephrectomy is usually necessary for cure.

Asymptomatic Bacteriuria

Asymptomatic bacteriuria, as noted previously, is a common and generally benign infection.^{7,23} Pyuria is often present, especially in elderly people, and is a predictor for subsequent symptomatic UTI in some groups. Causative uropathogens are the same as those causing UTIs in the same population. Screening for and treatment of asymptomatic bacteriuria is generally not warranted.⁷ However, patients at high risk for serious complications warrant a more aggressive approach to diagnosis and treatment, including pregnant women and patients undergoing urologic surgery. Current management strategies in patients with a renal transplant, including long-term antimicrobial prophylaxis, help prevent both asymptomatic bacteriuria and symptomatic urinary infection. It is not clear, however, whether screening for or treatment of asymptomatic bacteriuria in such patients is worthwhile.⁷ Some authorities advise treatment of asymptomatic bacteriuria found in patients with anatomic or functional abnormalities of the urinary tract, diabetic patients, and patients with urea-splitting bacteria, such as *P. mirabilis*, *Klebsiella* species, and others.²³ Evidence-based guidelines for screening and treatment of asymptomatic bacteriuria in these populations are needed.

Asymptomatic bacteriuria in catheterized patients in hospitals and long-term care facilities, although thought to be generally benign, represents a large reservoir of antimicrobial-resistant

urinary pathogens that increases the risk of cross-infection among catheterized patients and results in frequent inappropriate antimicrobial use.²⁹

UROLOGIC EVALUATION

Urologic consultation and evaluation of the urinary tract should be considered in patients who present with symptoms or signs of obstruction, urolithiasis, flank mass, or urosepsis. Similarly, such an evaluation should be considered for those patients with presumptive uncomplicated or complicated UTI who have not had a satisfactory clinical response after 72 hours of treatment to exclude complicating factors. Contrast-enhanced CT scanning of the kidneys is the most effective imaging modality in adult patients with renal infection because of its superior resolution and sensitivity in detecting renal abnormalities and perirenal fluid collections.³⁷ Spiral (helical) CT may be superior to conventional CT.³⁸ Non-contrast-enhanced spiral CT is a rapid, safe, and sensitive method for evaluating patients with suspected renal stones. Renal ultrasound is useful for detection of stones and abscesses and is often more readily accessible than CT. However, it is less sensitive than CT for detection of many of the conditions present in patients with complicated UTI. The role of magnetic resonance imaging remains to be determined. Radionuclide imaging procedures have no role in the evaluation of adults with UTI, although they are very useful in children with pyelonephritis (see Chapter 61). A plain abdominal radiograph may be used to detect gas in the urinary tracts of diabetic patients with suspected pyelonephritis, but it is not as sensitive or specific as CT.

Excretory urography and cystoscopy in women with recurrent cystitis rarely demonstrate abnormalities or alter management³ and are therefore not recommended. Likewise, routine urologic investigation of young women with acute pyelonephritis is generally not cost effective and has a low diagnostic yield, although it is reasonable to obtain such an evaluation after two episodes of pyelonephritis or if any complicating factor is present (see Fig. 51.1). A urologic evaluation is probably not necessary in a man who has had a single UTI with no obvious complicating factors and whose infection responds promptly to treatment.

Tuberculosis of the Urinary Tract

R. Kasi Visweswaran, Suresh Bhat

DEFINITION

Tuberculosis (TB), caused mostly by *Mycobacterium tuberculosis*, affects 15 to 20 million people worldwide, half of whom are infectious. About 8 million people develop active disease annually from the stage of asymptomatic infection.¹ The World Health Organization estimates that between 1999 and 2020, nearly 1 billion more people will be newly infected if control measures are not improved. In developed countries, TB commonly affects older individuals and ethnic migrants. The incidence of TB is 100 times greater in human immunodeficiency virus (HIV)-infected subjects.² TB also is more common in patients with renal disease. In some endemic areas, TB has been reported to occur in up to 8.7% of subjects on hemodialysis, 9.3% of renal allograft recipients, and 12.3% of children with nephrotic syndrome.³

Genitourinary TB occurs in about 5% of active cases in the non-HIV-infected population.⁴ It is almost always secondary to a symptomatic or asymptomatic primary lesion in the lung. Renal involvement may also occur as a complication of miliary (septicemic) TB.

ETIOLOGY

The tubercle bacillus is a nonmotile, nonsporing, strictly aerobic straight or slightly curved rod-like bacillus that is weakly gram positive and acid and alcohol fast. Mycobacteria have a lipid shell (“lipid barrier”) containing mycolic acid that resists proteolysis and uptake into phagolysosomes; muramyl dipeptide, which stimulates a T-cell response that elicits the characteristic granuloma; and cell wall glycolipids that inhibit macrophage function. This surrounding coat of inert lipids and surface proteins allows mycobacteria to survive inside phagocytes, where they may remain dormant for years.⁵

Whereas most TB is due to *M. tuberculosis*, other mycobacteria may rarely cause clinical disease, especially in immunocompromised hosts. These include *M. avium-intracellulare*, *M. kansasii*, *M. bovis*, *M. fortuitum*, and *M. szulgai*. However, most cases of genitourinary TB are due to *M. tuberculosis*.⁵

PATHOGENESIS

The clinical and pathologic manifestations of TB depend on the virulence of the organism and the effectiveness of the host response. The host response may lead to complete containment of infection or result in an illness of varying severity. Strain differences may also determine whether an infected person

develops primary TB, reactivation TB, or a chronic asymptomatic infection.

When an infected droplet with the size of 1 to 5 μm is deposited in the respiratory tract, tonsillar fossa, or gastrointestinal tract, a primary focus develops with the formation of a nonspecific asymptomatic granuloma. The organisms from the primary focus drain to the regional lymph gland, causing its enlargement, resulting in the *primary complex*. This is often asymptomatic and self-limited.

Bacilli from the regional lymph node may also enter through the thoracic duct into the blood, resulting in silent dissemination to various sites, including the cortex of the kidneys (Fig. 52.1). Here they elicit an inflammatory response resulting in granuloma formation that may heal and form a scar, remain dormant for many years, or rupture into the proximal tubule of the nephron. The bacilli in the nephron are trapped at the level of the loop of Henle, where they multiply. The relatively poor blood flow, hypertonicity, and high ammonia concentration in the renal medulla impair the immune responses and favor the formation of medullary granulomas. These granulomas (tuberculomas), which contain macrophages, may undergo coagulative necrosis, forming cheese-like caseous material (Fig. 52.2), and occasionally rupture into the calyx.⁶

The renal medulla is the most common site of involvement of clinical renal TB and is usually unilateral.⁷ When this caseous focus ruptures into the collecting system, cavities and ulcers are formed, and involvement of renal papillae may lead to sloughing and papillary necrosis. Healing in the kidney occurs by fibrosis and scarring, resulting in strictures and obstruction. Calcification commences intracellularly by the accumulation of phosphate ions from the disintegration of nucleoproteins and calcium ions from cell membrane damage. These lesions may harbor live mycobacteria, and such dystrophic lesions should be considered active disease and not a sign of healing. Dystrophic calcification of damaged structures may result in a nonfunctioning kidney called “putty” or “cement” kidney. Spread of TB to contiguous structures may occur; ureteritis is common and may result in strictures and obstructive uropathy (Fig. 52.3).

The bladder may develop hyperemia near the ureteral orifice, followed by superficial ulcers and granulomatous changes involving all layers (pneocystitis). Healing by fibrosis at the ureteral orifice results in a refluxing “golf-hole” ureter. Extensive fibrosis of the bladder wall results in a thick, small-capacity bladder (“thimble” bladder; Fig. 52.4). Bladder infection may also rarely result from instillation of bacille Calmette-Guérin (BCG) in the bladder as part of treatment of superficial bladder carcinomas.

Figure 52.1 Pathogenesis of urinary tuberculosis.

Involvement of the genital tract is also common. As many as 70% to 80% of men with TB of the urinary tract have epididymitis, prostatitis, seminal vesiculitis, orchitis, or cold abscesses. In women, genital tract involvement is less common; but if it is present, it usually presents as salpingitis that is often diagnosed during investigation for infertility.

Transplanted kidneys may also transmit TB to their recipients.⁸

CLINICAL MANIFESTATIONS

Urinary tract TB may be asymptomatic or mimic other disorders. It may present with constitutional symptoms or symptoms

related to the lower urinary tract, abdomen, or genitalia (Fig. 52.5). A high index of suspicion enables early diagnosis. Most patients are between 20 and 40 years of age, with a male to female ratio of 2:1. Because active genitourinary TB presents 5 to 15 years after primary infection, it is relatively rare in children. Increased risk factors for TB include close contact with sputum smear-positive individuals, vagrancy, social deprivation, neglect, immunosuppression, HIV infection or acquired immunodeficiency syndrome (AIDS), diabetes mellitus, renal failure, and other debilitating illness.

Nearly 25% of patients have no clinical or laboratory evidence of abnormality and the diagnosis is made on investigation for other diseases, during surgery, or at autopsy. Another 25%

Figure 52.2 Renal tuberculosis. A cut section of kidney showing areas of cavitation and caseation necrosis (white chalky material).

Figure 52.3 Multiple ureteral strictures. Strictures (arrows) associated with dilated ureter, infundibular stenosis (IS), and caliectasis (C) are seen in this intravenous urogram. (Courtesy Professor K. Sasidharan, Kasturba Medical College, Manipal, India.)

have asymptomatic urinary abnormalities, usually persistent asymptomatic pyuria or hematuria. In patients with persistent pyuria, conventional urine cultures do not yield any growth, and the urine is usually acidic, hence the term *acid-sterile pyuria*. Of the patients who are symptomatic, lower urinary tract symptoms, such as frequency, urgency, dysuria, nocturia, frank pyuria, or hematuria, occur in more than 75%. Increased urinary frequency is one of the early symptoms and results from inflammation of the bladder. The defect in the urinary concentrating mechanism explains the nocturia.

Recurrent bouts of painless macroscopic hematuria should alert the clinician to the possible diagnosis of urinary TB, although glomerular diseases, for example, IgA nephropathy, should also be considered. Macroscopic hematuria in urinary TB is a result of bleeding from the ulcerating lesions, inflammation of the urothelium, or rupture of a blood vessel in the vicinity of a cavity. Colicky pain may occur as a presenting manifestation of urinary TB when it is associated with stone, clot, or acute obstruction.

Figure 52.4 Cystogram showing thimble bladder.

Clinical Features of Urinary Tuberculosis

Features	Frequency (%)	Symptoms
Asymptomatic	25	Detected during autopsy, surgery, or investigations for other diseases
Asymptomatic urinary abnormalities	25	Persistent pyuria, microscopic abnormalities, hematuria
Lower urinary tract symptoms (most common)	40	Frequency, urgency, dysuria, incontinence, nocturia, suprapubic pain, perineal pain
Male genital tract involvement	75	Epididymitis, hemospermia, infertility, reduced semen volume
Female genital tract involvement	<5	Amenorrhea, infertility, vaginal bleeding, pelvic pain
Constitutional symptoms	<20	Fever, reduced appetite, anorexia, weight loss, night sweats
Miscellaneous	—	Urolithiasis, hypertension, acute kidney injury, chronic kidney disease, abdominal colic, abdominal mass

Figure 52.5 Clinical features of urinary tuberculosis.

In advanced disease, frequency and urgency related to reduced bladder capacity (thimble bladder) occur. Incomplete emptying, increased susceptibility to infection, and secondary vesicoureteral reflux may also occur. In chronic ureteral obstruction, enlargement of the kidney, infection, or perinephric collection leads to a dull aching loin pain. Severe suprapubic pain with backache and dysuria suggests acute tuberculous cystitis.

Episodes of pyuria, which may suggest secondary bacterial infection or drainage of a caseous focus into the collecting system, may also be a manifestation of renal TB. Persistence of pyuria after appropriate therapy should lead to an evaluation for urinary TB.

Long-standing renal TB may result in mild tubular proteinuria (<1 g/24 h) in up to 50% of patients. About 15% have proteinuria of more than 1 g/24 h, and nephrotic syndrome due to amyloidosis may develop in some patients. Rare cases of mesangial proliferative glomerulonephritis have also been reported.

Anemia is seen in less than 20% of patients with nonmiliary disease, but the frequency is higher in those with renal dysfunction.⁹ A few patients have nephrogenic diabetes insipidus. Renal tubular acidosis may occur. Hyporeninemic hypoaldosteronism may result from the tubulointerstitial injury secondary to obstructive uropathy.¹⁰ Renal function is usually normal, but chronic kidney disease may develop if both kidneys are extensively damaged.

Some patients may present with renal failure, pyuria, microscopic hematuria, and proteinuria, in whom the urine cultures for mycobacteria are repeatedly negative. These patients respond favorably to antituberculous chemotherapy combined with corticosteroids. The kidneys are of normal size and show diffuse interstitial nephritis, with caseating granulomas containing the bacilli in 75% of the biopsy samples.¹¹ Hypertension is unusual in renal TB, but intimal proliferation of vessels near inflamed areas may lead to segmental ischemia and renin release.¹² In association with a nonfunctioning kidney, nephrectomy may help improve the hypertension. Relief of any obstruction may also help lower the blood pressure. Nephrolithiasis may occur in 7% to 18% of patients. Secondary infection with *Escherichia coli* may be seen in 20% to 50% of patients.

As discussed earlier, genital involvement is common in men with urinary TB. Epididymitis may present with scrotal discomfort, mass, or a cold abscess that may rupture, leading to a non-healing posterior scrotal sinus. Thickening of the vas deferens may result in the “beaded” vas. TB of the prostate may present with lower urinary symptoms and perineal pain. The prostate may be hard or boggy. Penile and urethral TB may present with strictures, fistulas, ulcers, or papillonecrotic skin lesions. Hemospermia, reduction of semen volume, and infertility are other manifestations of genital involvement. Direct spread of *M. tuberculosis* to the sexual partner is possible.

In women, the association between genital and renal TB is rare, occurring in 5% of cases. The major manifestation of genital involvement in women is infertility resulting from adherent salpingitis. Secondary amenorrhea, vaginal bleeding, and pelvic pain caused by inflammation may occur.

Constitutional symptoms, such as fever, weight loss, night sweats, fatigue, and anorexia, occur in less than 20% of patients and indicate active infection in other organs or secondary bacterial infection of the urinary tract. A careful examination to identify pulmonary, lymph node, or skeletal TB must be undertaken in all patients who present with constitutional symptoms. The chest radiograph may show evidence of active or healed tuberculous lesions in more than half of cases.

PATHOLOGY

Urinary TB may present as a miliary or ulcerocavernous pathologic process. The miliary form of TB is rare and is seen particularly in immunosuppressed individuals. The gross appearance of

Figure 52.6 Tuberculous granuloma. The granuloma comprises Langhans giant cells (two large cells in the center), surrounding epithelioid cells, and a rim of lymphocytes. (Courtesy Dr. Sathi Bai Panikker, Kottayam, India.)

the kidney is characteristic; the cortex is studded with yellowish white, hard, pinhead-sized nodules that on microscopy show several coalescent granulomas with central caseation.

In the more common ulcerocavernous form, the kidneys will initially appear normal or show yellow nodules on the outer surface. On cut section, granulomas and ulcers in the renal pyramid or medullary cavities may be seen. Larger cavities filled with caseous material communicating with the collecting system may also occur. Other gross findings include multiple ulcers in the infundibular region of the calyces, calyceal stenosis with caliectasis, ulcers or strictures of the ureter with hydronephrosis, pyonephrosis, subcapsular collections, and perinephric abscesses. The bladder may show ulcers or be grossly fibrotic and contracted.

On microscopy, in early disease, neutrophilic infiltration with phagocytosis of the bacilli may be present. Subsequent histologic features depend on the virulence of the organism and the cell-mediated immunity. In those with an effective cell-mediated response, granulomas, characterized by the presence of macrophages with engulfed bacilli surrounded by epithelioid cells and Langhans giant cells, are seen (Fig. 52.6). There is often a cuff of lymphocytes and plasma cells surrounding the lesion. Healing occurs by fibrosis and scarring. In those with a less effective immune response, there is caseating necrosis, characterized by amorphous cheese-like eosinophilic material replacing the normal tissue architecture. The presence of caseous necrosis generally implies that the lesion is active. Later, this may calcify. Dystrophic calcification suggests activity rather than healing.

Kidneys may also be enlarged from amyloidosis or diffuse proliferative glomerulonephritis. In tuberculous interstitial nephritis, interstitial granuloma formation associated with normal-sized kidneys and negative urine cultures is seen.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

A high index of suspicion is necessary to diagnose genitourinary TB. Elderly subjects, those recently exposed to infection, immunocompromised individuals, and patients with TB elsewhere are at high risk. Suspicion may also occur if there is sterile pyuria, which is present in 50% of patients. The tuberculin test (Mantoux test) is useful for proving infection (or prior immunization with BCG), but not necessarily disease. A positive test response only suggests prior exposure to the antigen and does not indicate active infection. A negative test response in the absence of

an immunosuppressed state rules out tuberculous infection. However, patients with uremia, particularly in the setting of malnutrition, may display anergy and have a false-negative test result.¹³

Isolation of *M. tuberculosis* by urine culture is the definitive diagnostic test. Fully voided early morning urine samples for 3 to 5 consecutive days are cultured on two standard solid mycobacterial culture media: the egg-based Lowenstein-Jensen medium and the agar-based Middlebrook 7H10 medium. These transparent media enable earlier visualization of microcolonies, which grow by 6 to 12 weeks. Sensitivity tests are performed to choose the optimum chemotherapeutic agents. However, this may take an additional 6 to 12 weeks. Any tissue specimen submitted for mycobacterial culture should be macerated with sterile sand by a mortar and pestle before inoculation. Direct demonstration of acid-fast bacilli in urine by Ziehl-Neelsen stain is not reliable for diagnosis because *Mycobacterium smegmatis*, a saprophyte, may be easily mistaken for *M. tuberculosis*.

Rapid methods for diagnosis of TB are increasingly available. With use of the radiometric broth method for acid-fast bacilli isolation, a positive growth can be obtained in about 9 days. Serologic tests with the soluble antigen fluorescent antibody test and the polymerase chain reaction can be used for early diagnosis of TB.¹⁴ Enzyme linked immunospot assays are used as in-vitro diagnostic tests and they measure T cell specific *M. tuberculosis* antigens. The test results are unaffected by prior tuberculin testing or low CD4 counts.¹⁵ Another reliable and simple test using whole blood is based on quantifying the interferon- γ released from the white blood cells that have been exposed to some of the mycobacterial antigens. The availability of the result in 24 hours is the main advantage.¹⁶ Sonographically guided fine-needle aspiration cytology is useful as a diagnostic tool in defining the granulomatous nature of the lesion in patients with positive urine culture. Histologic diagnosis is made by identifying the pathologic triad of caseating necrosis, loose aggregates of epithelioid histiocytes, and Langhans giant cells.

Imaging studies are essential to assess the extent and severity of involvement once a diagnosis of genitourinary TB is made. Extensive dystrophic calcification in advanced renal TB is described as “cumulus cloud” calcification (Fig. 52.7). Plain radiographs of chest and spine show active or healed tuberculous lesions in 60% to 70% of patients. Abnormalities in the excretory urogram may be seen in 70% to 90% of patients. Minimal erosion of the tip of the calyx with spasticity, incomplete filling, distortion, infundibular stenosis, hydrocalicosis, multiple ureteral strictures, hydronephrosis, hydroureter, or nonvisualization of the kidney may be present. The renal pelvis, which may be dilated initially, may eventually be obliterated, leading to a distorted appearance called hiked-up pelvis (Kerr kink sign). Irregularities or multiple strictures lead to a beaded or corkscrew appearance of the ureter or hydronephrosis. Later, thickening and straightening of the whole ureter may occur (“pipe-stem” ureter). The bladder may appear irregular and fibrosed, and vesicoureteral reflux may occur. Antegrade or retrograde pyelography can identify the number, length, or site of ureteral strictures and assist in placement of a ureteric stent across the stenotic segment.

High-resolution ultrasound is useful to rule out obstruction and to study the parenchyma closely to identify granulomas, small abscesses, bladder mucosal thickening, or calcification (Figs. 52.8 and 52.9).¹⁷ The earliest finding is mucosal thickening and calyceal irregularity.

Figure 52.7 Plain radiograph showing calcified kidney.

Figure 52.8 High-resolution ultrasound scan of the kidney showing a sloughed necrosed papilla (P) in the calyx. (From reference 18, with permission of the American Institute of Ultrasound in Medicine.)

Computed tomography (CT) is the most sensitive method for identifying renal parenchymal scarring, calcification, and cavity lesions (Figs. 52.10 and 52.11). Cortical thinning is a common CT finding and may be either focal or global. These imaging modalities are helpful in the follow-up of patients with cavities or mass lesions in the kidney. Cystoscopy under general

Figure 52.9 High-resolution transverse ultrasound scan of the kidney showing mucosal thickening (arrows) of calyces and the pelvis (P). There are calcifications of the wall of the calyx and pelvis (arrowheads). A parenchymal cavity (C) is also shown. anesthesia helps visualize the mucosal lesions, the golf-hole ureteral orifice, or the efflux of toothpaste-like caseous material. Biopsy during the acute stage is avoided for fear of dissemination of TB.

TB mimics numerous diseases. Chronic nonspecific urinary infections may be confused with renal TB, and this is confounded by the fact that secondary bacterial infection may complicate 20% of cases of renal TB. Absence of response to usual antibiotics should arouse suspicion of urinary TB. Conditions causing recurrent painless hematuria, such as IgA nephropathy and schistosomiasis (see Chapter 54), are often misdiagnosed as TB in endemic areas. In interstitial cystitis, lower urinary symptoms similar to tuberculous cystitis may occur, but the urinalysis does not show gross pyuria, and cultures for acid-fast bacilli are negative. On radiologic examination, chronic pyelonephritis, renal papillary necrosis, medullary sponge kidney, calyceal diverticulum, renal carcinoma, xanthogranulomatous pyelonephritis, and multiple small renal calculi have to be differentiated from TB. Of late, a few cases of pseudotuberculous pyelonephritis have been reported in which caseating granulomas resembling TB were observed in

Figure 52.11 Renal tuberculosis. CT scan shows an enlarged left kidney with multiple cavities present bilaterally (marked 1, 2, 3, and 4). (Courtesy Professor K. Sasidharan, Kasturba Medical College, Manipal, India.)

the renal parenchyma but no mycobacteria or other microorganisms were detected in the renal tissue or urine culture.¹⁸

NATURAL HISTORY

The prognosis of genitourinary TB depends on the host resistance and the load and virulence of the organism. In many cases, foci in the urinary tract remain dormant indefinitely. Progression occurs through formation of tuberculous granuloma, caseation, ulceration, and dystrophic calcification. Most manifestations result from the complications, which can be prevented by timely chemotherapy and appropriate surgical intervention when indicated. With the advent of effective chemotherapeutic measures, the long-term complications and sequelae of TB have decreased significantly.

TREATMENT

Genitourinary TB is usually amenable to medical treatment. Many antituberculous drugs reach the kidneys, urinary tract, urine, and cavitory lesions in high concentration, and there are fewer organisms in the lesions compared with cavitory lung lesions. A wide variety of antituberculous agents are also available ([Fig. 52.12](#)).

A short-course regimen is recommended.¹⁹ Treatment is started with daily rifampin (600 mg), isoniazid (300 mg), and pyrazinamide (1500 mg) in the morning. Unless the culture sensitivity indicates otherwise, pyrazinamide is discontinued after 2 months, and isoniazid and rifampin are continued for another 4 months. If the patient is very sick with irritative bladder symptoms, streptomycin in daily doses of 1 g may be added during the first 2 months. However, if the patient is older than 40 years, the daily dose of streptomycin is reduced to 0.75 g with periodic monitoring for ototoxicity and vestibular toxicity.

If the probability of drug resistance is high, ethambutol in daily doses of 800 to 1200 mg may also be used in the first 2 months. Longer courses of antituberculous treatment ranging from 9 months to 2 years are useful in patients who do not tolerate pyrazinamide, those responding slowly to a standard regimen, those with miliary or central nervous system disease, and children with multiple-site involvement.

Fixed-dose combinations of anti-TB drugs incorporating two or more drugs in the same tablet have advantages. These include increased compliance, administration of adequate dose, minimization of inadvertent medication errors, and avoidance of drug resistance.

Antituberculous Drugs					
Drug	Dose Form	Dosage	Side Effects	Mode of Action	Remarks
Isoniazid	Tablet: 100 mg, 300 mg	5 mg/kg daily (oral) (maximum, 300 mg/day)	Peripheral neuritis, hepatitis, hypersensitivity reactions	Bactericidal for groups I and II	Pyridoxine (50 mg) prophylaxis necessary
Rifampin (Rifampicin)	Capsule or tablet: 150, 300, 450 mg	10 mg/kg daily (oral) (maximum, 600 mg/day)	Hepatitis, febrile reactions, acute interstitial nephritis	Bactericidal for groups I, II, and III	
Pyrazinamide	Tablet: 400, 500 mg	25 mg/kg daily (oral) (maximum, 2 g/day)	Hepatotoxicity, hyperuricemia	Bactericidal for group II	Combination with aminoglycoside useful
Streptomycin	Powder for injection: 1 g	15 mg/kg daily IM (maximum dose, 1 g; dose reduced in those >40 years of age)	Ototoxicity, nephrotoxicity	Bactericidal for group I	
Ethambutol	Tablet: 100, 400 mg	15–25 mg/kg daily (oral) (maximum, 2.5 g/day)	Optic neuritis (reversible), rash	Bacteriostatic for groups I and II	Used to inhibit development of resistant mutants; use with caution in renal failure
Thiacetazone	Tablet: 150 mg	150 mg (oral) (not for intermittent therapy)	Rashes, exfoliative dermatitis, hepatic failure	Bacteriostatic and inhibits emergence of isoniazid resistance	Not used in renal failure
Ciprofloxacin	Tablet: 250, 500 mg	500–1000 mg (oral)	Hypersensitivity, drug interaction		Not used in children
Ofloxacin	Tablet: 200, 400 mg	400–500 mg (oral)			Not approved by FDA for tuberculosis
Capreomycin Kanamycin		15–30 mg/kg daily IM	Ototoxicity, nephrotoxicity	Bactericidal for group I	Avoided in older patients and those with renal failure

Figure 52.12 Antituberculous drugs. The main drugs are listed with dosage form, dosage, side effects, and mode of action. *M. tuberculosis* exists as 3 subpopulations. Group I is extracellular, occurs mainly in cavitating lesions, and respond to streptomycin, isoniazid and rifampin. Group II reside intracellularly in macrophages, replicate slowly, and respond to pyrazinamide, isoniazid or rifampin. Group III organisms exist within closed caseous lesions, survive better in neutral pH, replicate slowly, and respond best to rifampin.

During treatment, healing by fibrosis may lead to obstruction of one or both ureters, with hydronephrosis, parenchymal damage, and renal failure. Dehydration or salt depletion may occur from tubulointerstitial damage, resulting in altered tubular function. Adrenal involvement may contribute to salt wasting. Oliguric acute renal failure caused by allergic interstitial nephritis may occur in patients receiving intermittent rifampin therapy.

Surgical Treatment

The role of surgical treatment in urinary TB is limited. For ureteral strictures, timely introduction of stents across the narrow segment may avoid the need for major surgical procedures. Two broad types of surgical treatments are considered.

Reconstructive surgery involves the correction of obstruction to the ureter by pyeloplasty, ureteroureterostomy, correction of reflux by ureteral reimplantation, and increasing the bladder capacity by augmentation cystoplasty, which involves anastomosis of an isolated segment of bowel to the contracted bladder.

Ablative surgery involves removal of the diseased parts together with the infected material containing the dormant organisms. The need for removal of a unilateral nonfunctioning kidney is controversial. Because prolonged antituberculous treatment for 18 to 24 months effectively sterilizes caseous and

calcified masses of the tuberculous cement kidney, nephrectomy is advocated only in cases of secondary sepsis, pain, bleeding, uncontrollable hypertension, or continued positive urinary cultures. Tuberculous abscesses can be aspirated under ultrasound or CT guidance and antituberculous drugs directly instilled into the cavity.

Treatment Regimens in Special Situations

Women During Pregnancy and Lactation

Most antituberculous drugs are safe for use during pregnancy. However, streptomycin is ototoxic to the fetus and must be avoided. If a four-drug schedule is indicated, streptomycin is replaced by ethambutol. There is no contraindication to the use of these drugs during breast-feeding, and it is not necessary to isolate the baby from the mother. The baby should receive BCG immunization and isoniazid prophylaxis. Because rifampin interacts with the efficacy of oral contraceptive pills, women taking these agents together should be advised to take a higher dose of estrogen or to use alternative methods of contraception.

Treatment of Patients with Liver Disease

The usual short-term (6-month) chemotherapy regimen can be used in patients with liver disorders if there is no evidence of

chronic liver disease, hepatitis virus carrier state, past history of acute hepatitis, or excessive alcohol consumption. In chronic liver disease, isoniazid and two of the nonhepatotoxic drugs (streptomycin and ethambutol) can be used for 8 to 12 months. If rifampin is used, liver function should be closely monitored. Pyrazinamide is contraindicated. In those with acute hepatitis unrelated to TB or its therapy, it would be safer to defer the chemotherapy until the acute hepatitis has resolved. If immediate treatment of TB during acute hepatitis is mandatory, streptomycin plus ethambutol for a period of 3 months followed by isoniazid and rifampin for 6 months is advised.

Treatment of Patients with Renal Failure

In patients with renal failure, isoniazid, rifampin, and pyrazinamide, which are eliminated by the biliary route, can be given in normal dosages. Those receiving isoniazid should also be given pyridoxine (50 mg/day) to prevent peripheral neuropathy. Because streptomycin and ethambutol are excreted by the kidney, dosage modification of these drugs is necessary in renal failure. Streptomycin (15 mg/kg) is administered every 24 to 72 hours for a creatinine clearance between 10 and 50 ml/min and every 72 to 96 hours for a creatinine clearance of less than 10 ml/min to maintain a therapeutic peak level of 20 to 30 µg/ml. Monitoring for high-pitched tinnitus or sense of fullness in the ears and audiography may be useful. For ethambutol, the dose is administered every 24 to 36 hours if the creatinine clearance is between 10 and 50 ml/min and every 48 hours if the creatinine clearance is below 10 ml/min. Monthly questioning for symptoms of visual dysfunction (alterations in visual fields, acuity, and blue-green color vision) with early referral for ophthalmic examination may identify ethambutol toxicity early with potential reversibility.

Treatment in Renal Allograft Recipients

A modified treatment with adjusted doses of isoniazid and ethambutol for 18 months, combined with ofloxacin 200 mg twice daily for the first 9 months and pyrazinamide 750 mg twice daily for the first 3 months, has been recommended.²⁰ If rifampin is used in those who are receiving a non-cyclosporine-based immunosuppressive regimen, the maintenance dose of prednisolone may have to be doubled.

Treatment in AIDS

Short-term chemotherapy is sufficient. If the follow-up cultures are positive, prolonged therapy for up to 2 years may be needed on the basis of antibiotic sensitivity.

Patients Who Fail Treatment

Failure to show clinical or radiologic improvement with treatment may signify poor compliance, inadequate regimen and dosage, incorrect diagnosis, multidrug-resistant TB, delayed response, or the phenomenon of paradoxical reaction known as immune reconstitution inflammatory syndrome. This syndrome is characterized by unexpected worsening of symptoms or appearance of new lesions like lymphadenopathy, serosal effusions, and pleural infiltrates. This syndrome is more common in those prescribed antiretroviral treatment for coexisting HIV and TB infections.²¹

Monitoring of Patients

After 2 months of intensive chemotherapy, urine is cultured for *M. tuberculosis* for 3 consecutive days. If cultures remain positive,

sensitivity is done and treatment modified accordingly. After completion of treatment, all patients should have three consecutive early morning samples of urine for *M. tuberculosis* culture, and this is repeated after 3 months and 1 year. Intravenous urography or ultrasound is repeated at the end of 2 months and at the completion of treatment to detect any evidence of obstruction. In cases of renal calcification, the patient should be evaluated yearly by three early morning samples of urine for culture of mycobacteria and by plain radiography of the abdomen for up to 10 years because calcification may harbor *M. tuberculosis* and may progress to destruction of the kidney.

Fungal Infections of the Urinary Tract

Carol A. Kauffman

Funguria is a frequent finding in hospitalized patients. Almost always, the organisms found in urine are *Candida* species, although several other yeasts and less commonly molds and endemic fungi also can be found (Fig. 53.1). Candiduria is not a symptom, a sign, or a disease but frequently is a perplexing phenomenon for the physician to deal with. In reality, most patients with candiduria are asymptomatic and have colonization of the bladder or of an indwelling urinary catheter. The most difficult diagnostic problem that is encountered is determining when infection rather than colonization is present. Diagnostic tests to define whether candiduria is related to colonization or infection have not been standardized; similarly, diagnostic studies to localize the site of infection to either the bladder or the kidneys are not well established. In contrast to the situation with candiduria, growth in urine of organisms such as *Blastomyces dermatitidis*, *Aspergillus* species, and *Cryptococcus neoformans* almost always reflects disseminated infection. This chapter outlines an approach to the diagnosis and treatment of candiduria and other fungal urinary tract infections.

CANDIDA

Epidemiology

Candida species are common inhabitants of the perineum but are not found in urine in appreciable numbers in healthy hosts. However, a variety of predisposing factors allow these commensals to grow in the urine and in some instances to invade the bladder or the upper urinary tract and to cause infection. These factors are more commonly encountered in hospitalized patients, especially those in the intensive care unit and in patients in long-term care or rehabilitation units.¹ In a recent point prevalence survey of positive urine cultures obtained from hospitalized patients, *Candida* species were found in nearly 10% of specimens and were the third most common microorganism isolated from urine.²

The risk factors for candiduria, but not specifically for *Candida* urinary tract infection, have been established in several prospective surveillance studies and a few case-controlled studies.³⁻⁵ Risk factors for candiduria are found to be similar in most of these studies and include increased age, female sex, antibiotic use, urinary drainage devices, prior surgical procedures, and diabetes mellitus (Fig. 53.2). In the largest surveillance study, urinary drainage devices, mostly indwelling urethral catheters, were present in 83% of patients who had candiduria; only 11% of patients with candiduria had no other risk factor.³ In a multicenter study from Spain assessing candiduria in patients in an intensive care unit setting, independent risk factors associated with candiduria were age older than 65 years, female sex, diabetes mellitus, prior antibiotics, mechanical ventilation, parenteral

nutrition, and length of hospital stay before admission to the intensive care unit.⁴ A case-controlled study that compared candiduria due to *C. glabrata* with that due to *C. albicans* found that both species were associated with female sex, intensive care unit stay, and antibiotic use, whereas *C. glabrata* was more common in subjects with diabetes and in those who had received prior treatment with fluconazole (to which this species is typically resistant).⁵ Most of the patients in these studies most likely had colonization and not infection with *Candida*.

Prospective controlled studies assessing risk factors for well-documented urinary tract infection due to *Candida* species have not been performed because firm diagnostic criteria for *Candida* urinary tract infection have not been established. However, clinical experience suggests that infection is more common in diabetic subjects and in those who have partial or complete urinary tract obstruction.

Pathogenesis

Candida has the propensity to cause disease by either the hematogenous or ascending route. This contrasts with urinary tract infections due to most bacteria, in which infection ascends from bladder to the collecting system of the kidney.

The pathogenesis of hematogenous seeding of *Candida* to the kidney was shown with animal models.⁶ Multiple microabscesses develop throughout the cortex, with the yeasts penetrating through the glomeruli into the proximal tubules, where they are shed into the urine (Fig. 53.3). Healthy animals eventually clear the infection, but immunocompromised animals do not. Consistent with the experimental studies, renal microabscesses have been identified in 90% of patients with invasive candidiasis at autopsy.⁷ The pathogenesis of ascending infection with *Candida* is not known. No animal model exists for this condition. Obstruction and stones are important factors in some patients, but specific mechanisms of adherence and subsequent growth in the collecting system have not been studied.

Microbiology

C. albicans accounts for 50% to 70% of all *Candida* urinary isolates; *C. glabrata*, present in approximately 20% of isolates, is the second most common,³ *C. tropicalis* and *C. parapsilosis* are less common, and other species are rarely isolated. Certain populations of patients have a predominance of *C. glabrata*. For example, older adults frequently have *C. glabrata* isolated from urine, but urine cultures from neonates rarely yield *C. glabrata*. In a prospective survey of candiduria in renal transplant recipients, *C. glabrata* represented 53% and *C. albicans* only 35% of isolates.⁸

It is important to know the species causing candiduria for therapeutic reasons. Resistance to fluconazole, the primary agent

Risk Factors for Different Types of <i>Candida</i> Urinary Tract Infections	
Type	Risk Factors
Renal (hematogenous)	Neutropenia, recent surgery, central venous catheter, parenteral nutrition, antibiotics, dialysis
Lower urinary tract	Indwelling bladder catheter, older age, female, diabetes, obstruction, antibiotics, urinary tract instrumentation
Upper urinary tract	Older age, diabetes, antibiotics, obstruction, urinary tract instrumentation (e.g., nephrostomy tube, ureteral stent)

Figure 53.2 Risk factors for candiduria.

used for the treatment of *Candida* urinary tract infections, occurs commonly among isolates of *C. glabrata* and occurs in all isolates of *C. krusei*. In contrast, almost all isolates of *C. albicans*, *C. tropicalis*, and *C. parapsilosis* are susceptible to fluconazole.

Clinical Manifestations

Most patients with candiduria are asymptomatic, and indeed, most do not have infection. A large prospective surveillance study of patients with candiduria noted that less than 5% of patients with candiduria had any symptoms suggesting urinary tract infection.³ When patients have symptomatic cystitis or pyelonephritis, symptoms are indistinguishable from those noted with bacterial infections. Cystitis is manifested by dysuria, frequency, and urgency, and patients with upper tract infection can present with fever, chills, and flank pain. Uncommonly, urinary obstruction occurs from formation of a bezoar or fungal ball in the bladder or the collecting system. This may cause hydronephrosis, and uncommonly, acute kidney injury occurs.

Patients who have had seeding of the renal parenchyma during an episode of candidemia manifest the symptoms and signs associated with invasive candidiasis and not those of urinary tract infection. Chills, fever, hypotension, and other manifestations of sepsis are commonly noted in patients who are candidemic.

Diagnosis

Major diagnostic difficulties are encountered in trying to differentiate contamination of a urine specimen from colonization

Figure 53.3 Hematogenous renal candidiasis. **A**, Multiple small abscesses are grossly obvious throughout the kidney. **B**, Histopathologic demonstration of a microabscess in the cortex of the kidney due to *Candida albicans* (Methenamine silver stain, yeast shown in grey-brown color).

of the bladder or of an indwelling urethral catheter from invasive infection of the bladder or the kidney. Contamination is most easily differentiated by simply repeating the urine culture to determine if the candiduria persists. It may be necessary to obtain the second urine specimen by sterile bladder catheterization if the patient is unable to accomplish a clean-catch collection. In those patients who have an indwelling urethral catheter, the catheter should be replaced and a second urine specimen collected. For either of these circumstances, if the repeated culture yields no yeasts, no further diagnostic studies or therapeutic interventions are needed.

Distinguishing colonization from infection is not straightforward. In comparison with bacterial urinary tract infections, in which the diagnosis is based on appropriate symptoms combined with the findings of pyuria and quantitative bacterial counts, no studies have established the importance of quantitative urine cultures or pyuria for the diagnosis of *Candida* urinary tract infection.¹

The techniques routinely used in most clinical laboratories for the detection of bacteria will also detect *Candida* in urine. However, *C. glabrata* grows more slowly than other species and more slowly than bacteria, and colonies may not appear for 48 hours, which is often after routine cultures of urine have been discarded in most laboratories.

The role of quantitative urine cultures to differentiate upper tract infection from bladder colonization was assessed by investigators in the 1970s and unfortunately showed broad ranges of

Figure 53.4 Photomicrograph of a renal tubular cast containing *Candida albicans*, showing both yeast forms and hyphae in a patient with fungal pyelonephritis.

Figure 53.5 Cystoscopic appearance of extensive cystitis caused by *Candida krusei*.

colony counts for both colonization and infection.^{9,10} In patients who did not have indwelling catheters, documented renal infection was found with colony counts as low as 10^4 yeasts/ml.¹⁰ For patients who had indwelling catheters, colony counts between 2×10^4 and 10^5 cfu/ml or more were noted, and there was no correlation with biopsy-proven renal infection. A murine model of hematogenous renal candidiasis documented that renal involvement could be seen with any concentration of *Candida* in the urine.¹¹

Pyuria is often not a helpful diagnostic criterion for infection in patients with candiduria. Concomitant bacteriuria is frequently noted in patients with candiduria and may be responsible for pyuria.¹ In patients who have an indwelling bladder catheter, pyuria is routinely noted, whether or not infection is present. In patients who do not have an indwelling bladder catheter or bacteriuria, the presence of pyuria is helpful.

Identification of casts containing yeasts in the urine appears to be specific for upper tract infection, but the technique is time-consuming, requires expert evaluation, and is not sensitive (Fig. 53.4). The finding of pseudohyphae in urine samples is no longer thought useful, especially because organisms such as *C. glabrata* cannot form pseudohyphae.

Imaging procedures, including abdominal ultrasound and computed tomography (CT), are essential to document obstruction at any level in the urinary tract and to determine the presence of fungus balls in bladder or kidneys.

In some patients, it is helpful to perform cystoscopy and biopsy of the bladder wall to determine whether inflammation is present and to evaluate the extent of invasion (Fig. 53.5). Retrograde studies can also be performed to establish whether obstruction is present.

Treatment with Systemic Antifungal Agents

Most patients who have candiduria do not need treatment with an antifungal agent. For patients who are asymptomatic, treatment should be given only to those who are at high risk for

development of candidemia or in whom the presence of candiduria, regardless of symptoms, is likely to represent disseminated infection. The newly revised guidelines for the management of candidiasis published by the Infectious Diseases Society of America include the following in this category: patients undergoing urologic procedures, very low birth weight infants, and neutropenic patients (Fig. 53.6).¹² Patients who have candiduria and who are to undergo a urologic procedure are at increased risk for development of candidemia and should be treated with an antifungal agent a few days before and after the procedure. Candiduria in neutropenic patients and in very low birth weight infants has a high probability of representing disseminated candidiasis, and thus these groups also should be treated with an antifungal agent. Interestingly, asymptomatic candiduria in the renal transplant patient does not appear to warrant systemic antifungal treatment unless obstruction is present or symptoms suggestive of local or systemic infection develop.

In non-high-risk patients who have asymptomatic candiduria, removal of an indwelling urinary catheter will eradicate candiduria in many patients.³ Follow-up urine culture can be performed a week later to determine if candiduria has cleared. If catheterization cannot be discontinued, the existing catheter should be removed and a new one inserted. This will often eradicate candiduria transiently, but it is highly likely that the organisms will return within a short time. Relief of obstruction, whether it is present in the upper or lower urinary tract, is essential for the long-term eradication of *Candida* from the urinary tract.

Patients who have symptoms suggestive of cystitis or pyelonephritis and in whom bacteria as well as *Candida* are found in the urine culture specimen should be treated initially with an antibacterial agent. If no bacteria are present, treatment with an antifungal agent is appropriate (see Fig. 53.6). Eradication of the organism with antifungal therapy is more likely if the indwelling catheter is also removed.¹³ Oral fluconazole is the drug of choice. A loading dose of 400 mg should be given, followed by 200 mg daily for a total of 14 days.^{12,13} Fluconazole is excreted as active

Figure 53.6 Treatment recommendations for candiduria and *Candida* urinary tract infections.

Treatment Recommendations for <i>Candida</i> Urinary Tract Infections		
Asymptomatic candiduria	No treatment indicated except: Urologic surgery	Treat a few days before and after the procedure with fluconazole 200–400 mg qd or Amphotericin 0.3–0.6 mg/kg/d
	Low birth weight infant or neutropenic patient	Treat as for disseminated candidiasis/candidemia
Cystitis	Preferred: oral fluconazole, 200 mg qd × 14 d	Alternatives include: Amphotericin 0.3–0.6 mg/kg/d × 1–7 d Flucytosine 25 mg/kg qid × 7–10 d
Pyelonephritis	Preferred: oral fluconazole, 200–400 mg qd × 14 d	Alternatives include: Amphotericin 0.5–0.7 mg/kg/d × 14 d Flucytosine 25 mg/kg qid × 14 d
Renal (hematogenous)	Treat as for disseminated candidiasis/candidemia	
Fungus balls	Surgical removal and Fluconazole, 200–400 mg qd	Alternatives include: Amphotericin 0.5–0.7 mg/kg/d Flucytosine 25 mg/kg qid

drug in the urine and should effectively treat all *Candida* species, with the exception of those *C. glabrata* that are fluconazole resistant and *C. krusei*. The dosage of fluconazole should be reduced by 50% in patients with a creatinine clearance of 20 to 50 mL/min per 1.73 m² and by 75% when the creatinine clearance is below 20 mL/min per 1.73 m².

The possibility of drug-drug interactions should be evaluated before fluconazole is ordered. Phenytoin, warfarin, cyclosporine, tacrolimus, rifabutin, and sulfonylurea agents are some of the drugs for which serum concentrations will increase and may reach toxic levels after the addition of fluconazole to the therapeutic regimen.

The other available azole agents, itraconazole, voriconazole, and posaconazole, are not excreted into the urine as active drug. Whether tissue concentrations might be high enough to treat invasive kidney or bladder infections is not known, and there is no clinical experience to suggest that they will be effective.

Intravenous amphotericin B deoxycholate is effective in treating *Candida* urinary tract infections but should be reserved for those patients who have upper tract infection or for whom fluconazole therapy has failed. The toxicity, especially nephrotoxicity (see Chapter 66), associated with this agent precludes its use in many patients. The usual dosage is 0.3 to 0.6 mg/kg per day for 5 to 7 days, although this may be extended to 2 weeks for those with complicated upper tract infection.¹² Infusion-related side effects that are seen in some patients, even when they are treated with the lowest dosage, are rigors, fever, nausea, vomiting, and headache.

Lipid formulations of amphotericin are not recommended for treatment of fungal urinary tract infections. It is likely that the mechanism that leads to decreased nephrotoxicity with the addition of the lipid component precludes the drug's effectiveness by failing to achieve adequate levels in the urinary tract. Failures have been reported in a few patients.¹⁴

One of the few uses of flucytosine is for the treatment of *Candida* urinary tract infections. This agent, which is excreted into the urine as active drug in high concentrations, should be used only when fluconazole is not tolerated or the organism is

fluconazole resistant. The usual dosage is 25 mg/kg orally every 6 hours for 7 to 10 days. Most species of *Candida*, with the exception of *C. krusei*, are susceptible to flucytosine, but resistance emerges quickly when this agent is used alone. Serious adverse effects of flucytosine include bone marrow suppression and hepatotoxicity. These effects are dose related, and the risk increases greatly with renal failure.

The echinocandins caspofungin, micafungin, and anidulafungin have minimal or no excretion into the urine as active drug. It is possible that the tissue concentrations achieved with these agents may be adequate to treat invasive *Candida* infections of the bladder or kidney. However, there are limited clinical data, and echinocandins currently cannot be recommended for the treatment of *Candida* urinary tract infections.

Local Antifungal Administration

Continuous bladder infusion of amphotericin, 50 mg in 1 liter of sterile water with a triple-lumen catheter, is sometimes used to treat *Candida* bladder infection. Bladder irrigation will clear candiduria more quickly than systemic antifungal agents will.¹⁵ However, the effect is brief, and recolonization occurs within 1 to 2 weeks. It is likely that irrigation eliminates bladder colonization in the short term, but it is not evident that bladder infection can be treated with this maneuver. Recent literature suggests that amphotericin bladder irrigation is a strategy rarely needed given the need for catheter placement and the availability of more convenient treatment options, and this method of treatment is not recommended.^{12,16} The one exception might be lower tract infection with *C. krusei* and *C. glabrata*, which are resistant to fluconazole and flucytosine.

In the setting of obstruction due to a fungus ball, irrigation through a percutaneous nephrostomy tube with amphotericin is recommended in addition to systemic antifungal therapy with fluconazole.¹² Absorption of amphotericin does not occur, and direct infusion is not nephrotoxic. Ultimately, surgical or endoscopic removal of the mass of fungal organisms is essential to eradicate the organism.

OTHER YEASTS

Cryptococcus neoformans infection in immunosuppressed hosts, especially patients with acquired immunodeficiency syndrome (AIDS), is a systemic illness with involvement of many organs, including the genitourinary tract. In autopsy series, kidney involvement has been noted in 25% to 50% of patients who died of cryptococcosis, but it is usually asymptomatic. The prostate is also frequently infected and can be a reservoir for *C. neoformans* infection. Viable *Cryptococcus* organisms have been shown to persist in the prostates of AIDS patients who had been successfully treated for cryptococcal meningitis.¹⁷ Given the current use of fluconazole for treatment of cryptococcal meningitis and the high levels achieved by this agent in the prostate, this has become less of an issue.

Isolated prostatitis and epididymo-orchitis have been reported rarely in the absence of systemic cryptococcosis. The diagnosis is usually made at the time of biopsy of a mass or nodule; granulomatous inflammation is typically seen with highly encapsulated budding yeast shown by special stains. Treatment of local genitourinary tract cryptococcal infection is fluconazole, 400 mg daily for 6 to 12 months.

Saccharomyces cerevisiae rarely has been described as a cause of urinary tract infection. The presentation is the same as that noted with *Candida* species, and in those clinical microbiology laboratories that do not identify yeasts in urine to the species level, this organism will not be differentiated from *Candida*. *S. cerevisiae* is often resistant to fluconazole, and successful treatment may require amphotericin.

ASPERGILLUS AND OTHER MOLDS

The urinary tract is an uncommon site of infection with molds. However, individual case reports have noted genitourinary infections due to a variety of molds, including the Zygomycetes, *Aspergillus*, *Penicillium*, and *Paecilomyces*.¹⁸ The most common mold infection is aspergillosis, as elsewhere in the body. Hematogenous spread to the kidney with invasive disease in immunosuppressed patients results in numerous renal microabscesses and infarcts. This may be an incidental finding in the face of massive dissemination at autopsy. Patients who have symptomatic urinary tract infection usually present with urinary tract obstruction due to masses of fungal elements causing fungal balls that can be visualized on CT scan or ultrasound examination. Treatment is surgical removal of the obstructing mass, often nephrectomy, and systemic antifungal therapy, usually with amphotericin. Mortality is extremely high.

ENDEMIC FUNGI

All of the major endemic mycoses have been reported to infect the genitourinary tract. For all of these organisms, infection is by hematogenous spread to the genitourinary tract. For upper tract infection, treatment is the same as that for disseminated infection. The treatment of focal infection, which is more likely to involve the lower genitourinary tract, is usually surgical removal of the infected tissue combined with antifungal therapy.

Blastomyces dermatitidis has the greatest propensity to cause symptomatic infection. In patients with disseminated blastomycosis, involvement of the genitourinary tract occurs in as many as a third of cases and usually is manifested by prostate or epididymal infection.¹⁸ In most cases, this involvement is discovered

incidentally when urine cultures yield the organism or when a biopsy is performed for a prostatic or epididymal mass.

Symptomatic genitourinary tract involvement with histoplasmosis is uncommon. However, at autopsy, kidney lesions are often found in patients who have disseminated histoplasmosis.¹⁸ Patients are usually asymptomatic in regard to urinary symptoms. Rarely, individual cases of testicular abscesses, epididymitis, and prostate nodules have been reported.¹⁹

Coccidioidomycosis rarely causes symptomatic urinary tract infection. However, autopsy series of cases of disseminated coccidioidomycosis have noted kidney involvement in more than 50% of cases.²⁰ The finding of *Coccidioides* species in the urine in the absence of symptoms in such patients is not uncommon. Localized infection, presenting as abscesses or mass lesions of the epididymis or prostate, also occurs in patients with disseminated coccidioidomycosis.¹⁸

The Kidney in Schistosomiasis

Rashad S. Barsoum

Schistosomiasis is a parasitic disease usually acquired by teenagers, often leading to complications that may extend into the fourth and fifth decades of life. It was known to the ancient Egyptians as “the bloody urine disease”¹ and is also known as bilharziasis in honor of its discoverer, Theodor Bilharz, the German physician who practiced in Egypt in the 1850s.

The life cycle of the parasite is shown in Figure 54.1. Infection is acquired through contact with contaminated waters in the ponds and slow-flowing canals originating from certain rivers, such as the Nile. Cercariae enter through the skin or mucous membranes and migrate through the lymphatics and blood circulation into the portal or perivesical venous system, where they mature into sexually differentiated adult worms and live in almost continuous copulation. Females leave the males only to lay eggs, traveling against the blood flow, aiming at the rectal or bladder mucosa. The ova are driven out by visceral contraction during defecation or urination in the respective excreta. Contact with fresh water within a couple of days allows the eggs to hatch, releasing miracidia, which infect specific snails. In this “intermediate” host, they mature asexually into cercariae, which are eventually released, searching for their “definitive” host, usually humans and occasionally apes and cattle. The snail demography defines the endemicity and frequency of schistosomiasis in different geographic regions. Because this is largely influenced by climatic factors such as temperature and humidity, it is possible to accurately monitor the global epidemiology of schistosomiasis by satellite remote sensing.²

About 200 million inhabitants of 76 countries on five continents are infected, and an additional 400 million are at risk. Of the infected subjects, 60% are symptomatic, 10% have serious sequelae, and 1% die of the disease each year, mainly in China, the Philippines, Egypt, Brazil, northern Senegal, and Uganda.

Only three species are responsible for almost all the morbidity from the disease (Fig. 54.2): *Schistosoma haematobium*, throughout Africa and adjacent regions; *Schistosoma mansoni*, in Africa, South America, and the Caribbean islands; and *Schistosoma japonicum*, in the Far East. *S. haematobium* affects the urinary tract, whereas *S. mansoni* and *S. japonicum* affect the colon and rectum, ultimately reaching the liver and inducing periportal fibrosis. Sporadically, all three species cause “metastatic lesions” when ova are driven by the blood stream to the lungs, brain, spinal cord, heart muscle, eyes, and other sites.³

Morbidity from infection is variable and depends on the virulence of the infective strains, host resistance, environmental factors, and standards of primary medical care. For example, chronic lower urinary tract disease among infected subjects is reported to vary from 2% in Nigeria in the west of Africa to 52% in Tanzania in the east.⁴

PATHOGENESIS

Schistosomes cause morbidity through two major mechanisms (Fig. 54.3): (1) local reactions around the ova deposited in different tissues and (2) systemic effects attributed to the host’s response to circulating antigens released from the worms or the ova.^{4,5}

The local reaction is a cell-mediated immune response to soluble egg antigens diffusing out of trapped ova through micropores in the eggshell. The initial response is innate, being driven by tissue macrophages, and involves natural killer cells, neutrophils, and complement. This is followed by a specific immune response orchestrated by the helper CD4⁺ T lymphocytes.

The schistosomal granuloma (Fig. 54.4) is composed of mononuclear cells, eosinophils, neutrophils, basophils, and fibroblasts, which are recruited and activated by a variety of T helper (Th) lymphokines as well as specific chemoattractants of parasitic origin. These cells are involved in the elimination of the parasite by direct phagocytosis (monocytes), lymphocytotoxicity (T lymphocytes), antibody-dependent cytotoxicity (eosinophils), and antibody- and complement-dependent cytotoxicity (neutrophils). Later, the granuloma is modulated by gradual switching from Th1 to Th2 activation, largely mediated by a change in the monokine profile that favors release of interleukin (IL)–4, which is associated with a phenotypic change of the committed tissue macrophages. At this stage, the intensity of the inflammatory reaction is reduced, and progressive fibrosis is induced largely through the release of IL-4, IL-5, IL-10, somatostatin, and transforming growth factor β . Finally, fibrotic granulomas in the bladder, lower ureters, and seminal vessels tend to become calcified.⁶

The systemic immune response is primarily a humoral reaction to circulating schistosomal antigens, which originate mainly from the worm’s digestive enzymes (gut antigens), with a minor contribution from the tegument and ova. The gut antigens consist of a positively charged glycoprotein and a negatively charged proteoglycan (circulating cathodal antigens and circulating anodal antigens, respectively). These antigens are present in most of the schistosomal immune complex-mediated lesions, particularly in glomeruli.⁷ The antibody response is biphasic, reflecting the successive Th1 and Th2 stages of lymphocyte activation. In the Th1 stage, B cells tend to synthesize IgM, IgG1, and IgG3 under the influence of IL-2. During the Th2 phase, IgG2, IgG4, and IgA predominate; these have a limited ability to fix complement and may even block its deposition, hence their importance in modulating the granulomas.^{4,6}

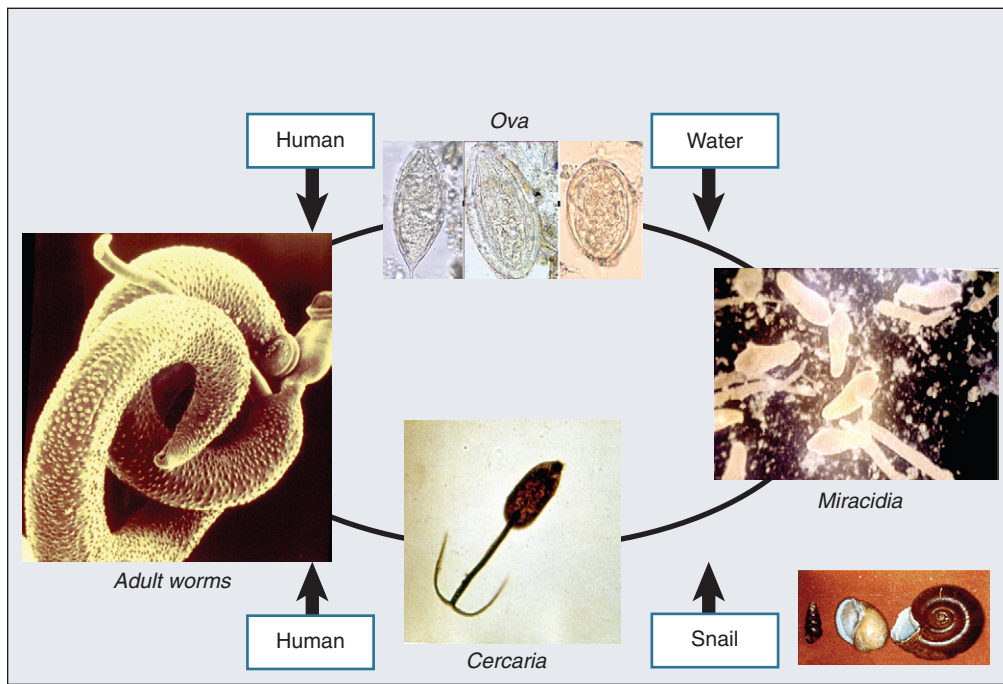

Figure 54.1 Life cycle of schistosomes.

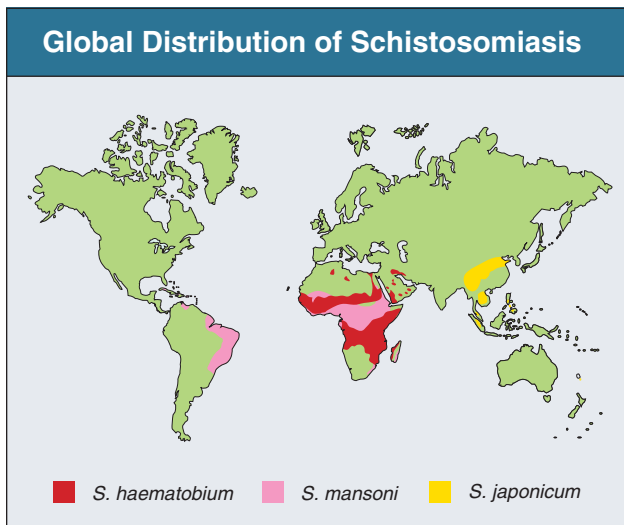

Figure 54.2 World map showing the geographic distribution of the main pathogenic schistosomes.

CLINICAL MANIFESTATIONS

Schistosomal lesions in the urinary system mirror the two major pathogenetic mechanisms. On one hand, there are local lesions, mostly affecting the lower urinary tract, caused by the local granulomatous response to *S. haematobium* ova.⁸ On the other hand are those lesions caused by immune complex deposition in the glomeruli, usually associated with *S. mansoni* infections of the intestine and less commonly with *S. haematobium* infections.⁹

Lower Urinary Schistosomiasis

The lower urinary tract is the site of *S. haematobium* infection. Clinical disease starts by the coalescence of multiple granulomas

that form small “pseudotubercles” in the bladder mucosa (Fig. 54.5). These may consolidate to form sessile, occasionally pedunculated masses or ulcerate, leading to painful terminal hematuria, the most typical presenting symptom. Ulcers eventually heal by fibrosis, with calcified granulomas under the atrophic and dirty mucosa, leading to the characteristic cystoscopic appearance of sandy patches and also the radiologic appearance of linear bladder calcifications. Similar lesions may occur in the lower ureters, bladder neck, seminal vesicles, and other organs in the vicinity (Fig. 54.6).

The bladder lesions predispose to secondary bacterial infection, particularly with *Pseudomonas* or *Proteus* species, after instrumentation. *Proteus* infection is notorious for favoring stone formation, which further complicates the scenario. The subsequent fibrotic process may involve the bladder neck, leading to outflow obstruction, or the vesicoureteral junction, leading to ureteral obstruction or vesicoureteral reflux. Involvement of the detrusor is a late event that may interfere with the motor function of the bladder, leading to an atonic or a hyperirritable viscus. Eventually, the bladder becomes a deformed, contracted, and calcified organ that accommodates a very small amount of urine that it can hardly void.

Bladder Cancer

Chronic bilharzial cystitis is precancerous. Up to 4.5% of patients with chronic urinary schistosomiasis develop bladder cancer, which is usually a squamous cell carcinoma (60%) or less commonly transitional cell carcinoma (20%) or adenocarcinoma (10%).¹⁰ The tumor, particularly when it is of the squamous cell type, remains localized for a long time before spreading to the surrounding pelvic tissues or distant site, thanks to the occlusion of lymphatics by the preceding fibrotic process.

Associated infection with human papillomavirus is encountered in about one fourth of cases, which suggests an etiologic role in malignant transformation.¹¹ Specific p53 gene mutations were detected in one third of cases.¹² This may be attributed to neutrophil-generated reactive oxygen molecules, cleavage of

Figure 54.3 Immune response to schistosomal infection. The local immune response to deposited ova leading to granuloma formation is shown on the left; all cells shown in the diagram, in conjunction with antibodies or complement, participate in eventual parasite elimination (see text). The systemic immune response is shown on the right; note the important role of impaired clearance of schistosomal antigens and IgA in the development of glomerular lesions. APC, antigen-presenting cell; IL, interleukin; NKC, natural killer cell.

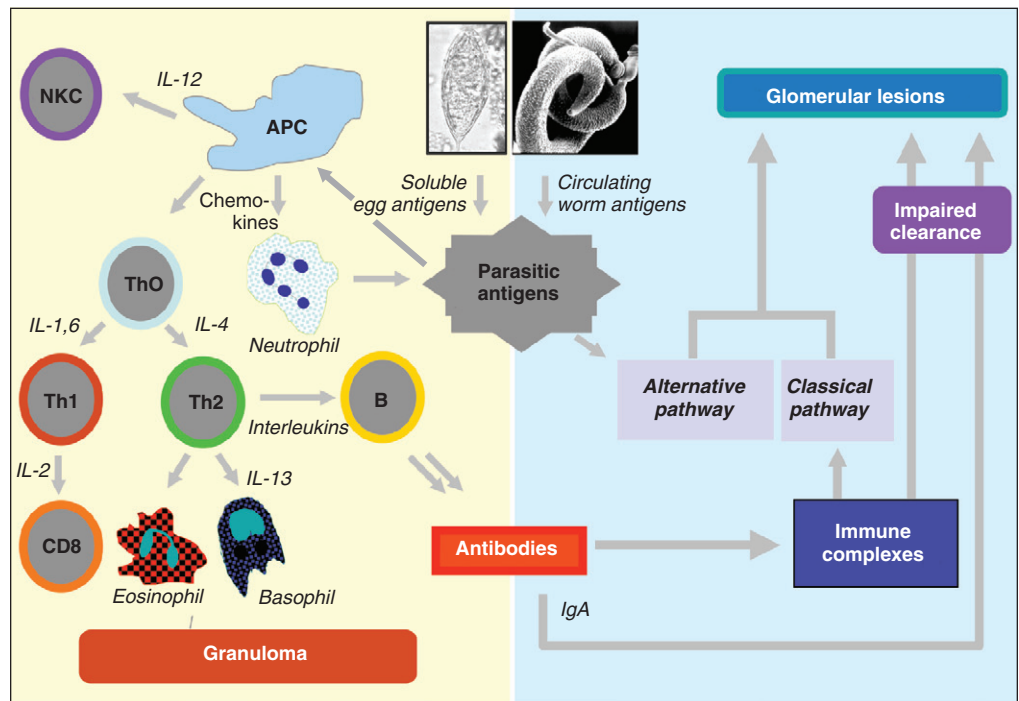

Figure 54.4 *Schistosoma haematobium* granuloma. Note the egg's terminal spike, which identifies *S. haematobium*, and the distortion of shell from proteases and oxidants released by the local neutrophil infiltration. (Hematoxylin and eosin; magnification $\times 500$.)

conjugated urinary carcinogens, or production of nitrosamines by bacterial enzymes.¹³

Development of malignancy is suspected when the symptoms of chronic cystitis exacerbate, along with recurrence of hematuria many years after the initial presentation and the passage of small pieces of necrotic tissue with urine (necroturia). A characteristic radiologic sign is the irregular "eating up" of the bladder calci-

fication on a plain radiograph. Cystography shows the tumor mass as an irregular filling defect or bladder ulcer. Cystoscopy shows the tumor (Fig. 54.7) and provides the means for a histologic diagnosis.

Upstream Consequences

Although ureteral strictures and calcifications are common, the hypertrophied upper ureteral musculature usually overcomes the lower obstruction, thereby limiting the upstream consequences. Nevertheless, hydronephrosis and progressive renal failure may develop when there is extensive ureteral scarring, in the presence of stones or secondary bacterial infection, or when the vesico-ureteral junction is incompetent (Fig. 54.8). The frequency of upper urinary tract disease from *S. haematobium* varies from less than 10% in Niger to 48% in Cameroon.

Interstitial Nephritis

Chronic pyelonephritis is the eventual outcome of complicated *S. haematobium* infection, resulting from obstruction, reflux, and bacterial infection. Granulomas have occasionally been seen in the renal interstitium (Fig. 54.9) but tend to be discrete and of no functional significance. Immune-mediated tubulointerstitial nephritis has been described with *S. mansoni* in humans, but the role of immune mechanisms remains questionable in *S. haematobium* pyelonephritis.

The typical pathologic picture is that of a scarred kidney with calyceal dilation, distortion, and atrophic parenchyma. There is dense interstitial infiltration, fibrosis, and periglomerular scarring. The glomeruli may show ischemic collapse or other schistosomal lesions, such as proliferative glomerulonephritis or amyloidosis.

The clinical picture is that of chronic tubulointerstitial nephritis (see Chapter 62), often associated with residual manifestations of lower urinary involvement. Hypertension is a late feature, being checked by tubular salt wastage during the early

phases of the disease. Anemia and osteodystrophy may be disproportionately severe because of the associated secondary distal tubular acidosis and nutritional deficiency in endemic areas.

Glomerulonephritis

Immune complex-mediated glomerulonephritis (GN) has been described in experimental¹⁴ and human⁹ infection, mainly with *S. japonicum* and *S. mansoni*, the latter accounting for most clinically significant disease in humans. *S. haematobium* GN is rare and usually subclinical, but a small epidemic of acute nephritis was reported in an Egyptian village where the infection had been recently introduced as a result of change in the agricultural irrigation system.¹⁵

Schistosomal gut antigens are present in circulating immune complexes as well as in the immune deposits in mesangial, sub-endothelial, and intramembranous locations. The presence of

Figure 54.7 Bilharzial bladder cancer.

Figure 54.8 Ascending cystogram showing right megaureter due to vesicoureteral reflux.

liver fibrosis is critical because it results in impaired hepatic clearance of schistosomal antigens and immune complexes, which are mostly generated within the portal venous tributaries. Evidence of autoimmune reactivity has also been reported, but its potential pathogenetic role is undefined.

Figure 54.9 Schistosomal chronic interstitial nephritis. Note the dense cellular infiltration and fibrosis, atrophic dilated tubules, and thickened vessels. Three glomeruli heavily infiltrated with amyloid are seen on the right side (arrows); a schistosomal granuloma is seen in the lower left corner (arrowhead). (Hematoxylin and eosin stain; original magnification $\times 75$.)

Most patients are 20- to 40-year-old men with evidence of hepatosplenic schistosomiasis. Renal involvement is asymptomatic in up to 40% of those, being identified by accidental or surveillance urinalysis, which may display microalbuminuria, various grades of proteinuria, or abnormal sediment. Some 15% of those with hepatosplenic schistosomiasis have overt GN, presenting with proteinuria and microhematuria, with or without the nephrotic syndrome, hypertension, and impaired renal function. Liver function test results are often normal. A polyclonal gammopathy is seen in most cases, whereas a monoclonal IgM response is seen in those with associated hepatitis C virus (HCV) and cryoglobulinemia. Rheumatoid factor activity and anti-DNA antibodies are detected in 5% to 10% of cases, particularly in association with *Salmonella* infection (see later discussion), but they do not correlate with clinical severity. Rheumatoid seropositivity is detected in much higher titers when HCV infection is associated.¹³

There are six histologic classes of schistosomal GN (Figs. 54.10 and 54.11).^{4,6,9,16} Class I (mesangial proliferative), class III (membranoproliferative), and class IV (focal segmental glomerulosclerosis) result from the deposition of immune complexes representing different stages in the evolution of “pure schistosomal” hepatosplenic disease. The main deposits in class I are schistosomal antigens, IgM, and C3; and in class III and class IV, IgG and IgA, usually without schistosomal antigens. The IgA deposits parallel the severity of proteinuria and mesangial proliferation. Impaired hepatic clearance and increased mucosal synthesis of IgA have been documented in those patients.¹⁷ Whereas class I lesions are seen in most asymptomatic cases, class III and class IV are usually symptomatic and progressive, even with eradication of the parasitic infection.

Class II (diffuse proliferative and exudative) is associated with coinfection with *Salmonella* strains, usually *Salmonella paratyphi* A in Africa and *Salmonella typhimurium* in Brazil, which are attached to specific receptors in the tissues of adult schistosomes. C3 and *Salmonella* antigens were detected in the glomerular capillary walls and the mesangium. In these patients, the clinical presentation is typical of acute postinfectious GN, associated with manifestations of *Salmonella*-related toxemia (fever, exanthema, and severe anemia).

Classification of Schistosomal Glomerulonephritis						
Class	Histology	Immunofluorescence	Etiologic Agent	Prevalence	Clinical Findings	Treatment of Renal Disease
I	Mesangioproliferative GN	IgM, C3 Schistosomal gut antigens	<i>S. haematobium</i> <i>S. mansoni</i> <i>S. japonicum</i>	27%–60% of asymptomatic patients, 10%–40% of patients with renal disease	Microhematuria Proteinuria	May respond to antiparasitic treatment
II	Diffuse proliferative exudative GN	C3, Salmonella antigens	<i>S. haematobium</i> <i>S. mansoni</i> + <i>Salmonella</i> species	Salmonella infections Reduced serum C3	Acute nephritic syndrome, toxemia	May respond to treatment of <i>Salmonella</i> and Schistosomal infections
III	Membranoproliferative GN	IgG, IgA, C3, schistosomal antigens	<i>S. mansoni</i> (<i>S. haematobium</i> ?)	7%–20% of asymptomatic patients and in 80% of patients with overt renal disease	Hepatosplenomegaly, nephrotic syndrome, hypertension, renal failure	No
IV	Focal segmental glomerulosclerosis	IgM, IgG (occasionally IgA)	<i>S. mansoni</i>	11%–38%	Hepatosplenomegaly, nephrotic syndrome, hypertension, renal failure	No
V	Amyloid	AA protein	<i>S. mansoni</i> <i>S. haematobium</i>	16%–39%	Hepatosplenomegaly, nephrotic syndrome, hypertension, renal failure	No
VI	Cryoglobulinemic GN	IgM, C3	<i>S. mansoni</i> + hepatitis C virus	Unknown	Hepatosplenomegaly, nephrotic syndrome, purpura, vasculitis, arthritis, hypertension, renal failure	Interferon + ribavirin, corticosteroids, immunosuppression, plasmapheresis

Figure 54.10 Classification of schistosomal glomerulonephritis.

Amyloid A protein deposits are detected by special stains or electron microscopy in up to 15% of biopsy samples from patients with class III and class IV, whereas amyloidosis may be the predominant lesion (class V) in less than 5% of patients with clinically overt schistosomal glomerulopathy. It occurs with heavy, often mixed infection regardless of the anatomic site. Minimal amyloid deposits do not seem to alter the clinical presentation or prognosis, but typical class V cases are grossly nephrotic and relentlessly progressive.

A class VI lesion was more recently described in patients with hepatosplenic schistosomiasis and HCV infection.¹⁶ This association is common, particularly in Egypt, where it is believed that the virus was acquired many decades earlier, when intravenous injections were used for mass treatment of schistosomiasis. Some evidence also suggests that the virus may be transmitted with the infected cercariae. Regardless of the mode of infection, those patients appear to have created a critical pool in the community that became a reservoir for the spread of infection by other means. The lesion consists of a mixture of mesangial proliferation, amyloid deposition, fibrinoid necrosis, and cryoglobulinemic thrombi in the glomerular capillaries with tubular casts. Patients present with chronic hepatitis, cirrhosis, nephrotic syndrome, cryoglobulinemic skin vasculitis, polyarthritis, and rapidly progressive renal failure associated with severe protein-calorie malnutrition.

DIAGNOSIS

Schistosoma haematobium Urinary Tract Disease

The bedside diagnosis of lower urinary schistosomiasis is easily made, particularly if patients present with the typical pattern of painful terminal hematuria after exposure to fresh river waters in an endemic area. Diagnosis is more difficult when the history of exposure is less convincing (e.g., swimming pools) or when the clinical presentation is atypical (such as bacterial pyelonephritis, typhoid, or amyloidosis).

The diagnosis is made by finding ova in a fresh urine sample, which is easy because of their abundance, large size, and typical appearance. Live ova, containing mobile miracidia, indicate active infection, whereas dead, calcified ova may continue to be shed from fibrotic lesions for many months or even years.

Serologic diagnosis is based on finding circulating schistosomal antigens or antibodies by gel diffusion, precipitation, complement fixation, chromatography, immunoelectrophoresis, indirect hemagglutination, microfluorometry, radioimmunoassay, or various forms of enzyme-linked immunosorbent assay (ELISA) techniques. The circumoval precipitin is most frequently used in clinical laboratories. These techniques are useful in confirming the diagnosis in the absence of ova, which occurs with old infections when the worms are sterile but continue to

Figure 54.11 Schistosomal glomerulopathy. **A**, Mesangial proliferative glomerulonephritis, hematoxylin and eosin stain (class I). **B**, *Schistosoma* and *Salmonella*-associated exudative glomerulonephritis, hematoxylin and eosin stain (class II). **C**, Membranoproliferative (mesangiocapillary) glomerulonephritis type I, hematoxylin and eosin stain (class III). **D**, Focal segmental glomerulosclerosis, Masson trichrome stain (class IV). **E**, Green birefringence under polarized light in a glomerulus with mesangial proliferation in a patient with mixed *S. haematobium* and *S. mansoni* infection, Congo red stain (class V). **F**, Amyloid deposits and cryoglobulin capillary thrombi (red stain) in a glomerulus displaying focal mesangial proliferation in a patient with schistosomal hepatic fibrosis and associated hepatitis C virus infection (class VI).

release their antigens. Serologic tests are also useful in assessing the response to treatment because titers usually become negative within 3 to 6 months of complete eradication of infection.

The radiologic appearances of bladder and seminal vesicle calcification are so typical that no further confirmatory tests are needed. Cystoscopic findings are equally pathognomonic although seldom required. Early pseudotubercles are easily distinguished from mycobacterial infection by their size and the surrounding mucosal pathologic changes. The presence of sandy patches with associated masses, polyps, and even neoplasms makes the diagnosis. Tissue biopsy confirms the parasitic nature of the lesions. Different imaging techniques (e.g., ultrasound, intravenous urography, voiding cystography) are useful in the diagnosis of upstream complications (see Chapter 58).

The main differential diagnosis for urinary schistosomiasis is tuberculosis, which also causes hematuria, strictures, back pressure, and chronic kidney disease. This differential can be resolved with appropriate parasitologic and bacteriologic techniques (see Chapter 52).

Schistosoma mansoni Glomerulonephritis

Overt glomerular disease in patients with hepatosplenic schistosomiasis is suspected in those who develop new hypertension, nephrotic or nephritic syndrome, or chronic kidney disease. Occult glomerular disease is detected by the presence of abnormal urinary sediment or renal function. Although renal biopsy is essential for the diagnosis and classification, none of the lesions

Figure 54.12 Stool smears showing living (A) and dead (B) *Schistosoma mansoni* ova. Species are identified by the lateral spike (arrows).

is pathognomonic unless schistosomal antigens are detected by immunofluorescence, which is unusual in clinically overt cases. Identification of *S. mansoni* eggs in the stools (Fig. 54.12) or submucosal rectal snips supports the diagnosis. Concomitant *Salmonella* or HCV infection can be detected by appropriate microbiologic tests. The various serologic abnormalities described are of limited diagnostic value, except the high rheumatoid factor, monoclonal IgM expansion, and low C4 that are typical of class VI.

Other glomerular disorders associated with hepatic fibrosis, such as secondary IgA nephropathy and hepatic glomerulosclerosis, may be considered in the differential diagnosis. However, in both these conditions, the renal lesions are relatively mild, presenting mainly with microhematuria but rarely with significant proteinuria or impaired renal function. The glomerular deposits are mostly mesangial, in contrast to those seen in schistosomiasis, in which subendothelial and intramembranous deposits may also be present.

Treatment

Schistosoma haematobium Urinary Tract Disease

S. haematobium is susceptible to antimony compounds, organophosphates (metrifonate), and niridazole, but the current drug of choice is praziquantel, the most effective and least toxic. It is administered as a single oral dose of 40 mg/kg body weight. Antiparasitic treatment cures the early bladder disease, yet it has no effect on sandy patches or other fibrotic lesions. Interestingly, ureteral distention with radiologic evidence of hydronephrosis may be reversed a few weeks after successful treatment.

Antibacterial therapy usually controls acute episodes of cystitis and pyelonephritis. However, it must be combined with simultaneous eradication of parasitic infection if it is still active, especially if the urinary bacterial infection is due to typhoid (*Salmonella typhi*).

Chronic fibrotic lesions are difficult to treat. Surgery or the placement of stents may be necessary for the relief of an obstructive lesion. However, particular caution is required in dealing with the vesicoureteral junction to avoid induction of reflux. Several plastic procedures are available to restore the distorted ureteral, bladder, or urethral anatomy. Associated bacterial infections may require long-term low-dose antibiotics.

Regular dialysis in such patients can be difficult owing to the negative effects of chronic infection; the associated schistosomal lesions in the liver, lungs, and other organs; and the comorbid impact of undernutrition, viral infection, or malignant disease. The same factors reflect on the outcome of renal transplantation, with the additional risk for urinary leakage, which is many-fold higher than usual due to the presence of fibrotic granulomas and anatomic distortion in the bladder wall. Reinfection with *S. haematobium* has also been described in patients living in an endemic area.¹⁸

Schistosoma mansoni Glomerulonephritis

S. mansoni is more resistant to treatment but does respond to single-dose treatment with either praziquantel (40 to 60 mg/kg body weight) or oxamniquine (single dose of 15 mg/kg body weight in South America or two doses of 15 mg/kg body weight given 12 hours apart in Africa). However, eradication of the parasite can be curative only in classes I and II. In class II, it must be combined with antibiotics for the control of *Salmonella* infection (usually ampicillin and cotrimoxazole). Antischistosomal therapy (praziquantel or oxamniquine) and immunosuppressive therapy are ineffective in all other classes.⁹

Dialysis may be difficult in those who reach end-stage renal disease because of the frequent presence of esophageal or gastric varices that carry the risk for bleeding with anticoagulation for hemodialysis. Endoscopy is essential before starting of regular hemodialysis, with prophylactic sclerotherapy if necessary. Although peritoneal dialysis is a viable option in some cases, it

is impossible in those with significant ascites because of the risk for excessive protein loss in the effluent.

The overall results of renal transplantation are not different from those with other renal disorders. Uncomplicated residual hepatic fibrosis in the recipient does not seem to significantly modify the pharmacokinetics of the immunosuppressive agents used in transplant recipients. However, variations in cyclosporine blood levels have been noted¹⁵ and attributed to altered absorption of the drug. Associated viral hepatitis may have a considerable impact on the protocols of donor selection and prophylactic immunosuppression and on the eventual outcome (see Chapters 98 and 101).

Recurrence of schistosomal GN has been described in a few patients,¹⁹ suggesting the persistent release of antigens from living worms. Prophylactic antischistosomal chemotherapy (i.e., praziquantel) is therefore recommended before renal transplantation for recipients known to have been previously infected with the parasite.

Glomerular Diseases Associated with Infection

Bernardo Rodríguez-Iturbe, Emmanuel A. Burdmann, Rashad S. Barsoum

GENERAL CHARACTERISTICS OF GLOMERULAR DISEASES ASSOCIATED WITH INFECTION

The observation of dark scanty urine in the convalescent period of scarlet fever is more than two centuries old. At the beginning of the last century, Clemens von Pirquet postulated that the disease resulted from antibodies that instead of having beneficial effects were pathogenic, an insight that constitutes a landmark that opened the field of immune-mediated renal disease.¹

Today, infection-related glomerulonephritis (GN) is uncommon and usually associated with debilitating conditions such as diabetes, malignant neoplasia, acquired immunodeficiency syndrome (AIDS), and alcoholism. Most infection-associated GN is due to *Streptococcus* (27.7%) and *Staphylococcus* (24.4%), but a wide variety of pathogens have been reported (Fig 55.1). GN usually results from glomerular deposition of immune complexes containing bacterial antigens, but other mechanisms may also occur (see later discussion). The most common sites of infection are the upper respiratory tract (23%), skin (17%), lung (17%), and heart valves (11.6%).²

Histologic Patterns and Pathogenesis

The histologic patterns and the most typical infectious diseases associated with them are shown in Figure 55.2. Mesangial proliferative GN is usually acute and self-limited. Microscopic hematuria and non-nephrotic proteinuria are present in association with deposits of IgG, IgM, and C3. Serum complement may be transiently decreased. Diffuse proliferative GN is also acute and self-limited if the infection is eradicated. IgG, IgM, and C3 deposits are prominent in the mesangium and glomerular capillaries, and electron-dense deposits are present in mesangial, sub-endothelial, and subepithelial locations. The immune complexes deposited in the glomeruli may or may not contain bacterial antigens, and cryoglobulins may be present. Staphylococcal infections, particularly methicillin resistant, may induce diffuse proliferative GN, likely resulting from bacterial wall superantigens that induce a nonspecific polyclonal immunoglobulin response, with crescent formation and exclusive or predominant IgA deposition. The clinical presentation is the acute nephritic syndrome. Membranoproliferative GN (MPGN) is commonly observed with chronic infections. The clinical presentation is usually the nephrotic syndrome with microscopic hematuria and variable degrees of hypertension. Immunoglobulins and C3 deposits are present. In the setting of liver disease (as in *Schistosoma mansoni* infection), IgA may be a predominant component of the immune deposits. Membranous nephropathy (MN) is

associated with chronic infections and presents as the nephrotic syndrome. Finally, vasculitis may develop in association with viral (especially hepatitis B virus and human immunodeficiency virus) or bacterial (rarely *Streptococcus*) infections.

Infection-related GN, especially when it is immune complex associated, occurs more frequently and has a worse prognosis in conditions in which there is difficulty clearing the infection or immune complexes. These conditions include human immunodeficiency virus infection, infections acquired in the neonatal period (when tolerance is often induced, such as is observed with hepatitis B virus infection), chronic liver disease, diabetes, and chronic alcoholism.

Infections may also be associated with renal disease by mechanisms that do not involve immune complexes. Focal segmental glomerulosclerosis (FSGS) with glomerular collapse (collapsing glomerulopathy) may occur with human immunodeficiency virus or parvovirus B19 infection. The hemolytic-uremic syndrome may result from verotoxin-producing *Escherichia coli* or *Shigella* species (see Chapter 28). Amyloidosis may result from chronic infections such as tuberculosis, leprosy, and schistosomiasis. Interstitial nephritis manifested as acute renal failure may result from several viral (especially Epstein-Barr virus) or bacterial (especially *Legionella*) infections. Hantavirus can also induce a hemorrhagic fever–renal failure syndrome in which infection of the interstitial capillaries and tubules leads to acute renal failure (see Chapter 66).

BACTERIAL INFECTIONS

Poststreptococcal Glomerulonephritis

Epidemiology

Poststreptococcal glomerulonephritis (PSGN) is more common in males (2:1) and usually affects children 2 to 14 years old. Traditionally, only certain nephritogenic strains of group A *Streptococcus pyogenes* result in GN. In the tropics and southern United States, PSGN usually follows streptococcal impetigo of M types 47, 49, 55, and 57. Throat infections with streptococcus types 1, 2, 4, and 12 are also nephritogenic.^{3,4} More recently, ingestion of unpasteurized milk contaminated with group C streptococcus (*Streptococcus zooepidemicus*) has caused clusters of cases and at least one large epidemic.⁵ The risk of nephritis in epidemics may range from 5% in throat infections to as high as 25% in M type 49 pyoderma. A genetic predisposition is suggested as there is an association of PSGN with HLA-DR4 and DR1 and higher attack rates in siblings than expected for the general population. The risk of PSGN is reduced by early antibiotic treatment.

Some Infectious Agents Associated with Renal Disease

Bacterial: <i>Streptococcus</i> (group A, <i>Streptococcus viridans</i>), <i>Staphylococcus</i> (<i>aureus</i> , <i>epidermidis</i>), <i>Salmonella</i> (<i>typhi</i> , <i>paratyphi</i>), <i>Escherichia coli</i> , <i>Leptospira</i> , <i>Treponema pallidum</i> , <i>Neisseria species</i> , <i>Mycobacterium leprae</i> , <i>Yersinia enterocolitica</i> , <i>Coxiella burnetii</i> , <i>Brucella abortus</i> , <i>Listeria monocytogenes</i>
Viral: Hepatitis A, B, and C; human immunodeficiency virus, varicella-zoster, parvovirus B19, cytomegalovirus, mumps, influenza, Epstein-Barr virus, coxsackievirus, and enteric cytopathic human orphan (ECHO) virus
Fungus: <i>Histoplasma capsulatum</i> , <i>Candida</i>
Protozoal: <i>Plasmodium</i> (<i>falciparum</i> , <i>malariae</i> , <i>vivax</i> , and <i>ovale</i>); <i>Trypanosoma</i> , <i>Toxoplasma</i>
Helminthic: <i>Schistosoma</i> (<i>mansoni</i> , <i>haematobium</i>), <i>Wuchereria bancrofti</i> , <i>Trichinella spiralis</i> , filaria (<i>Onchocerca volvulus</i> , <i>Loa loa</i>)

Figure 55.1 Some infectious agents associated with renal disease.

Renal Syndromes Associated with Infection

Clinical Presentation	Time Course	Pathologic Findings	Examples
Subclinical, microhematuria non-nephrotic proteinuria	Acute	Mesangioproliferative GN	Typhoid fever, <i>Pl. falciparum</i> PSGN
Acute nephritic syndrome	Acute	Diffuse proliferative GN	PSGN
Acute renal failure, nephrotic syndrome	Acute, chronic	Diffuse proliferative GN, crescents 1. IgM, IgG dominant 2. IgA dominant	1. Endocarditis, PSGN 2. Methicillin-resistant <i>S. Aureus</i>
Nephrotic syndrome reduced GFR	Chronic	1. MPGN type I ± cryoglobulins 2. Focal segmental glomerulosclerosis	1. Hepatitis C virus, infected AV shunts 2. HIV, parvovirus
Nephrotic syndrome	Chronic	1. Membranous nephropathy 2. Amyloid	1. Hepatitis B virus 2. Leprosy, <i>Schistosoma</i> , kala-azar
Acute renal failure, systematic symptoms, arthralgias, skin ulcers	Acute, chronic	Vasculitis, crescents, tubulointerstitial inflammation, atrophy and fibrosis	Hepatitis B virus, HIV
Hemolytic-uremic syndrome	Acute	Arteriolar thickening and occlusion, microthrombi, capillary wall thickening	<i>E. coli</i> O157-H7
Azotemia, non-nephrotic proteinuria, eosinophilia	Acute, chronic	Interstitial nephritis	Epstein-Barr virus, legionnaire's disease, Hantavirus, kala-azar

Figure 55.2 Renal syndromes associated with infection. AV, arteriovenous; GFR, glomerular filtration rate; GN, glomerulonephritis; HIV, human immunodeficiency virus; MPGN, membranoproliferative glomerulonephritis; PSGN, poststreptococcal glomerulonephritis.

PSGN is becoming less common in industrialized countries and is changing its epidemiologic pattern from one that primarily affects children to one that now occurs more commonly in debilitated elderly individuals, particularly alcoholics, diabetics, and intravenous drug users.² Nevertheless, PSGN remains common in developing countries, where it may affect 9.3 to 9.8 cases per 100,000 population,⁴ especially in communities with poor socioeconomic conditions. The reduction in incidence of PSGN likely relates to more rapid and frequent use of antibiotics. The common practice of fluorination of water may also be protective as fluoride reduces the expression of virulence factors in cultures of *S. pyogenes*.

Pathogenesis

Two nephritogenic streptococcal antigens have been identified: nephritis-associated plasmin receptor (NAPLr), which was identified as glyceraldehyde-3-phosphate dehydrogenase (GAPDH)⁶; and streptococcal proteinase exotoxin B (SPEB) and its more immunogenic precursor, zymogen.⁷ GAPDH and SPEB have been identified in renal biopsy specimens of acute PSGN, and antibody titers to both these antigens are elevated in most convalescent sera. GAPDH has been localized in areas of the

glomeruli with plasmin-like activity, suggesting a local direct mechanism of glomerular inflammatory damage, but it is not co-localized with complement or immunoglobulin.⁸ In contrast, SPEB is co-localized with both complement and IgG, suggesting a participation in the immune-mediated glomerular damage.⁹ Furthermore, SPEB is the only putative streptococcal nephritogenic antigen that so far has been demonstrated in the subepithelial electron-dense deposits known as humps (Fig. 55.3), the most typical histologic lesion of acute PSGN. In studies from Latin America and central Europe, SPEB but not GAPDH is usually detectable in renal biopsy specimens of PSGN patients.⁹ In contrast, GAPDH was present in PSGN in a study of Japanese patients.⁶ These contrasting results raise the interesting possibility that different streptococcal antigens are capable of inducing acute nephritis in different ethnic groups. Indeed, a study of the group C *S. zooepidemicus* strain that caused the epidemic outbreak in Brazil revealed an absence of the gene related to SPEB, which documents that this antigen was not involved in that epidemic.¹⁰

PSGN is thought to occur when persistent streptococcal infection results in antigenemia and the development of circulating immune complexes that primarily deposit in the

Figure 55.3 Poststreptococcal glomerulonephritis. **A**, A diffuse proliferative and exudative glomerulonephritis can be seen by light microscopy. **B-D**, Immunofluorescence showing the mesangial (**B**), starry sky (**C**), and garland (**D**) patterns. **E**, Immune electron microscopy showing the characteristic subepithelial electron-dense deposits (humps) (arrowheads), inside which streptococcal proteinase exotoxin B (SPEB) is demonstrated (arrows) (immunogold staining). BM, basement membrane; P, podocyte. (Reprinted with permission from reference 9.)

subendothelial and mesangial locations to initiate an inflammatory cascade with local complement activation and the recruitment of neutrophils and monocytes-macrophages. Subepithelial immune deposits (humps) develop because of the presence of cationic antigens (e.g., SPEB) or the dissociation of immune complexes in the subendothelial space with transit and re-formation on the outer aspect of the glomerular basement membrane. Cell-mediated immunity is supported by the presence of CD4 (helper) T lymphocytes. Cytokines also contribute to the local inflammation and injury. Urinary monocyte chemoattractant protein 1 correlates with the severity of proteinuria in the acute phase of PSGN.

Several issues remain unresolved. For example, immune complex disease generally results in activation of the classical complement pathway, yet in most cases, C4 levels are normal and only C3 is found in the deposits. This could be explained by the presence of antigens (such as GAPDH) that activate the alternative pathway. In some patients, C3Nef IgG antibodies have been demonstrated in sera that are capable of activating the alternative complement pathway. Activation of the lectin complement pathway by bacterial antigens has been postulated (see Chapter 16), but individuals genetically unable to activate this pathway may still develop PSGN.

Finally, the role of autoimmune mechanisms remains to be clarified. Rheumatoid factors (especially IgG rheumatoid factor) and cryoglobulins are found in the serum of one third of patients in the first week of the disease. Rheumatoid factors (antibody to IgG) have been shown in one third of the renal biopsy specimens and in the eluate from the kidney in a fatal case. Anti-IgG reactivity may result from the loss of sialic acid from autologous IgG

due to streptococcal neuraminidase (sialidase) or from binding of the Fc fragment of IgG to type II Fc receptors in the streptococcal wall.⁴ Additional manifestations of autoimmune reactivity include the anti-C1q antibodies, particularly in severe cases, and rarely anti-DNA reactivity, antineutrophil cytoplasmic antibody (ANCA), and autoimmune hemolytic anemia.⁴

Pathology

Renal biopsy shows a diffuse endocapillary GN with proliferation of mesangial and endothelial cells (see Fig. 55.3). There is glomerular and interstitial infiltration of monocytes and lymphocytes. Glomerular accumulation of neutrophils is common and is termed exudative GN. Glomerular immune deposits of C3 (100% of the cases), IgG (62%), IgM (76%), and properdin and the terminal membrane attack complex C5b-C9 (85% of the cases, usually codeposited with C3) are seen in glomerular capillary loops and in the mesangium. A seminal work by Sorger and colleagues¹¹ described three patterns of immunofluorescence in the glomeruli and their clinical correlations: the mesangial pattern of irregular and heavy immune deposits, the starry sky pattern of deposits scattered in mesangium and in capillary walls, and the garland pattern formed by gross deposits in the capillary loops (see Fig. 55.3). The garland pattern is clinically relevant because it is associated with heavy proteinuria and a large number of electron-dense subepithelial immune deposits. Ultrastructural studies demonstrate the subepithelial humps, which are typical although not pathognomonic of PSGN as they may also be observed in postinfectious GN of other causes (classically endocarditis-associated GN secondary to *Staphylococcus* infection), cryoglobulinemia, and lupus nephritis.

GN resolves by apoptosis of the excess cells. Residual renal injury is common, and biopsy specimens years later show variable degrees of focal glomerulosclerosis and mesangial expansion even in the absence of clinical disease. The clinical significance of these changes is undetermined.

Clinical Manifestations

Most patients give a history of a previous streptococcal infection, although it has often resolved at presentation. The incubation period is longer after skin infections (several weeks) than after throat infections (2 weeks).

The classic presentation is acute nephritic syndrome. Hypertension is found in 80% of patients. Edema occurs in 80% to 90% of cases and is the chief complaint in 60%; yet ascites is distinctly unusual.⁴ Primary sodium retention is the cause of expanded intravascular volume, hypertension, and edema. Plasma renin activity and aldosterone are reduced. Hematuria is universal and in 30% of cases is macroscopic.⁴

The nephrotic syndrome may occur at the onset in 2% of the children and 20% of adults. Rapidly progressive renal failure, resulting from extracapillary crescent formation, occurs in less than 1% of patients. Impaired renal function occurs in 25% to 40% of the children and in up to 83% of adults.

Positive cultures for *Streptococcus* are obtained in 10% to 70% of the cases during epidemics and in about 20% to 25% of sporadic cases. Antistreptolysin O (ASO) titers are increased in more than two thirds of patients with PSGN after throat infections, and anti-DNAse B titers are elevated in 73% of the post-impetigo cases. The streptozyme panel (which measures antibodies to four antigens, anti-DNAse B, antihyaluronidase, ASO, and antistreptokinase) is more sensitive, and the result is positive in more than 80% of subjects. Antibody titers to GAPDH and SPEB/zymogen, although more sensitive and specific,¹⁰ are not clinically available.

Serum C3 levels are depressed in more than 90% of patients in the first week of disease and return to normal in less than 2 months. C4, a measure of classical complement pathway activation, may be normal. Serum IgG and IgM are elevated in 80% of the cases, and in contrast with another poststreptococcal disease, rheumatic fever, IgA is normal. Cryoglobulins, elevated rheumatoid factor, and anti-C1q antibodies are present in up to one third of patients, and rare patients may have low titers of anti-DNA and ANCA.

Subclinical disease, manifested by microscopic hematuria and fall in serum complement, occurs four to five times more frequently than clinically overt disease and often involves siblings of index cases.⁷ On occasion, whole families have various manifestations of PSGN; it is thus important to inquire about a history of streptococcal infections and signs of nephritic syndrome among family members.

Management

Renal biopsy is not routinely indicated in PSGN but may be required to confirm the diagnosis when it presents with unusual clinical features, such as nephrotic proteinuria, decreased C3 levels lasting for more than a month (suggests lupus or hypocomplementemic MPGN), or increasing renal dysfunction (suggests crescentic GN).

Management includes culture and treatment of any remaining streptococcal infection. Early antibiotic treatment is likely to prevent PSGN. Treatment is with penicillin (1.2 million units of benzathine penicillin in adults or half this dose in small children, or alternatively, oral phenoxymethyl or phenoxyethyl

penicillin G 250 mg [adults] or 125 mg [children], every 6 hours for 7 to 10 days) or, in persons allergic to penicillin, erythromycin (250 mg every 6 hours in adults and 40 mg/kg in children, for 7 to 10 days). Cephalosporins may be used with equal or even better results.¹² Preventive antibiotic treatment is justified in populations at risk during epidemics and in siblings of index cases.¹³

Treatment of the acute nephritic syndrome includes restriction of fluid and sodium intake and the use of loop diuretics to treat circulatory congestion. An oral long-acting calcium antagonist is usually sufficient to control hypertension. Nitroprusside is used in exceptional cases with hypertensive encephalopathy. Dialysis (either hemodialysis or peritoneal dialysis) is required in 25% to 30% of adults but seldom in children.

Rare complications of acute PSGN include cerebral vasculitis, cerebral vasogenic edema, and posterior reversible leukoencephalopathy. The last is manifested by mental disturbances, visual hallucinations, headache, and convulsions and may be confused with hypertensive encephalopathy. The diagnosis requires the use of magnetic resonance imaging studies.

Anecdotal reports suggest that the rare patients with crescentic GN associated with PSGN may benefit from pulse methylprednisolone therapy, and if spontaneous improvement is not observed in 2 weeks, this therapy may be tried. The prognosis of crescentic PSGN is significantly better than that of crescentic GN due to other causes, but a complete recovery may be expected in less than half of the cases.

Prognosis

Most children with PSGN recover. In older subjects, there are higher acute complication rates, including a higher prevalence of renal impairment (60% to 70%), congestive heart failure (40%), nephrotic proteinuria (20%), and mortality (25%).³

After recovery, mild proteinuria (<500 mg/day) and microscopic hematuria may persist for up to 1 year without worsening the long-term prognosis. Nevertheless, some subjects, especially adults, may have persistent impaired renal function, proteinuria, or hypertension. However, end-stage renal disease (ESRD) occurs in less than 1% of the children observed for 1 to 2 decades after the acute attack.³

Certain epidemics have reported a high incidence of chronicity, perhaps because of a predominantly adult population.¹⁴ Risk factors for the development of chronic kidney disease include an onset with nephrotic-range proteinuria, older age, and coexistent diabetic nephropathy. Certain communities, such as Australian aborigines, also have a worse long-term prognosis.¹⁵

Endocarditis-Associated Glomerulonephritis

Community-acquired native valve endocarditis in the United States and western Europe has an incidence of 1.7 to 6.2 cases per 100,000 person-years, and as determined by population-based surveys, it is unchanged in the last 3 decades.¹⁶ In the United States, 15,000 new cases of infective endocarditis occur each year. The most common infecting bacteria are *Staphylococcus aureus* and *Staphylococcus epidermidis*; *Streptococcus viridans* and *S. pyogenes*; *Enterococcus faecalis*; and less commonly, *E. coli*, *Proteus*, and microorganisms of the *Bartonella* and *Candida* species. The more significant changes observed in the epidemiology are the reduction in the proportion of cases associated with rheumatic heart disease and the increase in health care-associated cases.¹⁶ Patients on chronic hemodialysis represent the most important subgroup, with 20 to 60 times the incidence in the general

population. In this population, synthetic grafts and long-standing venous dialysis catheters are significant risk factors. One third of patients with bacterial endocarditis develop impaired renal function, and the risk increases with age, a history of hypertension, thrombocytopenia, and prosthetic valve infection.

In a recent survey of 62 patients with infective endocarditis in whom renal tissue was available for study, biopsy and autopsy material demonstrated GN in 26%, of which many cases were pauci-immune renal vasculitis. Other pathologic changes included localized infarcts in 31%, half of which were septic, and interstitial nephritis, mostly attributable to antibiotics, in 10%. Cortical necrosis was found in 10% of the cases.¹⁶

The most common glomerular pathologic change is diffuse proliferative GN. Less commonly, focal GN, MN, and MPGN type I may be found. Crescent formation is found in about half of the proliferative GN forms. Widespread deposition of IgM, IgG, and C3 and electron-dense subendothelial, mesangial, and subepithelial deposits (which resemble poststreptococcal humps) are usually evident. In subacute endocarditis, focal segmental proliferative lesions with fibrinoid necrosis or capillary thrombi and mesangial immune deposits may be present. Tubulointerstitial cellular infiltration and variable degrees of atrophy and fibrosis may be seen. Intense eosinophilic infiltration should suggest another diagnosis, such as acute interstitial nephritis secondary to antibiotics.¹⁷

The pathogenesis of endocarditis-associated GN involves the deposition of immune complexes containing bacterial antigens in glomeruli, a mechanism similar to that proposed for PSGN. Cryoglobulins (of the polyclonal or type III type) are present in 50% of subjects and may be found in glomeruli. Some bacteria (classically methicillin-resistant *S. aureus*) express superantigens that can also activate T cells directly and lead to a polyclonal gammopathy and immune complex GN (see later discussion).

Clinical Manifestations and Diagnosis

Patients often present with fever, arthralgias, anemia, and purpura. Infective endocarditis may rarely present as primary renal disease without characteristic systemic symptoms. Classic findings in endocarditis, such as Osler's nodes, Janeway lesions, and splinter hemorrhages, are seldom seen. The renal manifestations usually are microscopic hematuria and mild proteinuria (except in cases with membranous GN, which may have proteinuria in the nephrotic range), with or without mild impairment in renal function (except in cases with renal vasculitis, in which renal failure is common). A rapidly progressive clinical course or nephrotic syndrome is unusual. Abnormal serologic test results include decreased C3 and C4 levels (consistent with activation of the classical complement pathway), high titers of rheumatoid factor, circulating immune complexes, and type III cryoglobulins. These serologic findings are observed in 50% of subjects with subacute bacterial endocarditis and in a higher proportion of patients with endocarditis-associated GN, although complement levels may be normal in superantigen-mediated GN. Cytoplasmic ANCA has been reported in rare cases with subacute endocarditis and GN.¹⁸

The differential diagnosis includes antibiotic-associated nephrotoxicity, interstitial nephritis, and embolism. Embolism may originate from the left side of the heart or from the right if the foramen ovale is patent. Microscopic or large emboli may occlude small or large vessels, the latter observed with fungal or *Haemophilus* endocarditis. Large emboli may produce flank pain, hematuria, and pyuria; microemboli produce local infarcts and microabscesses that give the kidney the classic "flea-bitten"

appearance. Interstitial nephritis is often associated with fever, eosinophilia, and eosinophiluria (see Chapter 60). Unfortunately, endocarditis-associated GN may also present with fever, and eosinophiluria can complicate crescentic nephritis of any etiology.

Antibiotic treatment for 4 to 6 weeks usually results in complete eradication of endocarditis with correction of serologic abnormalities, but microscopic hematuria, proteinuria, and elevation of serum creatinine may persist for months after eradication of the infection.¹⁹ Normalization of C3 levels during therapy correlates with a good outcome. In cases with crescentic GN, pulse corticosteroid therapy and plasma exchange have been used in addition to effective antibiotic therapy, but the value of these treatments remains undefined. The overall mortality of bacterial endocarditis is 20% and increases to 36% in the patients who develop renal failure.¹⁹

Staphylococcal Infections with Glomerular IgA Deposition

In 1995, Koyama and coworkers²⁰ described a novel form of severe GN associated with methicillin-resistant staphylococcal infections that presented with renal impairment, nephrotic proteinuria, and variable degrees of crescent formation. There was IgA dominant or codominant deposition in association with other immunoglobulin and complement deposits, and the patients had increased serum IgA levels and specific T-cell receptor V_{β}^{+} subsets during the course of the disease (Fig. 55.4). They postulated that staphylococcal superantigens were involved in the pathogenesis. The frequency of this condition is undefined, but it represents 1.6% of adult kidney biopsies in one institution.²¹

Clinical and Pathologic Characteristics

The initial cases all had severe GN with acute kidney injury, heavy proteinuria, and hematuria, but the condition may present with a milder clinical picture. Whereas most cases are associated with methicillin-resistant *Staphylococcus* infections, they may also occur in infection with methicillin-sensitive bacteria.²¹ Diabetic glomerulosclerosis frequently coexists.²² Complement levels may be low or normal.

Renal biopsy reveals variable degrees of mesangial and intracapillary hypercellularity with or without crescent formation. Interstitial fibrosis and tubular atrophy may be mild or severe. Electron microscopy shows electron-dense deposits in the mesangium in the glomerular basement membrane and in subendothelial areas. Large subepithelial electron-dense deposits are reported in some series. IgA deposition may be mild, moderate, or intense and is dominant or codominant with other Ig deposits. C3 deposits are usually present.

Pathogenesis

The pathogenesis of staphylococcal infection-related IgA GN is not entirely clear. Koyama and coworkers²⁰ have implicated staphylococcal superantigens that would bind directly to the major histocompatibility complex class II molecules on antigen-presenting cells, which then engage the V_{β} T-cell receptor region. The result is an intensive T-cell activation with cytokine production, which activates B cells that produce polyclonal IgG and IgA. They have identified a *S. aureus* cell envelope antigen that is co-localized with the glomerular IgA deposits.²³ Whether staphylococcus antigens are involved in the pathogenesis of IgA nephropathy (see Chapter 22) is a possibility that deserves further study.

Figure 55.4 Glomerulonephritis in a diabetic subject with methicillin-sensitive *S. aureus* infection. **A**, A diffuse exudative GN is present with neutrophil infiltration. **B**, Immunofluorescence shows IgA-dominant mesangial deposits. **C**, Electron microscopy shows dome-shaped subepithelial deposits (black arrow) and mesangial deposits (yellow arrow). (Courtesy Surya Seshan.)

Differential Diagnosis and Treatment

Antibiotic treatment of IgA-dominant staphylococcus-related GN is indicated because recovery of renal function may occur. Corticosteroid treatment is contraindicated, which makes it important to establish its differential diagnosis with IgA nephropathy, in which corticosteroids may be indicated in severe cases (see Chapter 22). Clinical characteristics that may be helpful in the differential diagnosis are the association with a staphylococcal infection (in contrast with upper respiratory infection in IgA nephropathy), the frequent occurrence of massive proteinuria (rare in IgA nephropathy), and the acute renal failure (uncommon in IgA nephropathy).

Shunt Nephritis

Atrioventricular shunts may become infected in about 30% of cases. GN may develop in 0.7% to 2% of those with infected atrioventricular shunts; this may occur 2 months to many years after insertion. The infective organisms are usually *S. epidermidis* and *S. aureus* and less frequently *Propionibacterium acnes*, diphtheroids, *Pseudomonas*, or *Serratia*. In contrast with atrioventricular shunts, ventriculoperitoneal shunts are rarely complicated with GN.

Patients present with insidious low-grade fever, arthralgias, weight loss, anemia, rash, hepatosplenomegaly, hypertension, and signs of increased intracranial pressure. Microscopic hematuria is present in 90% of subjects, and proteinuria is often in the nephrotic range. Serologic findings include positive rheumatoid factor titers, cryoglobulinemia, and decreased serum C3, C4, and CH50 levels. Raised c-ANCA titers may be found.²⁴

Renal histology shows MPGN type I in nearly 60% of the cases and non-IgA mesangial proliferative GN in the remainder. IgM, IgG, and C3 deposits are present in the glomerular capillary and mesangium.

Treatment requires antibiotic therapy and the prompt removal of the infected atrioventricular shunt, which is usually replaced by a ventriculoperitoneal shunt. Delay in diagnosis and in removal of the shunt worsens the prognosis of the renal lesion. In the event that dialysis is required, hemodialysis is the preferred modality because peritonitis complicating chronic peritoneal dialysis carries the risk of meningitis in patients with a ventriculoperitoneal shunt. Complete recovery occurs in more than half of the patients; persistent urinary abnormalities have been found in 22% and ESRD in 6% of the patients.

Glomerulonephritis Associated with Other Bacterial Infections

Osteomyelitis and intra-abdominal, pelvic, pleural, and dental abscesses can be associated with GN. Infection is usually present for several months before it is diagnosed. Renal disease may vary from mild urinary abnormalities to rapidly progressive GN, but the most frequent presentation is nephrotic syndrome. Unlike with other infection-associated GN, complement levels are often normal. Renal histology reveals MPGN, diffuse proliferative GN, or mesangial proliferative GN. Crescents may be present. Antibiotic treatment may result in recovery of renal function if it is started early.

Congenital and secondary (or early latent) syphilis may be associated with GN. In congenital syphilis, patients present with anasarca 4 to 12 weeks after birth. Nephrotic syndrome occurs in 8% of the patients and may be the primary clinical manifestation (as opposed to the more classic triad of rhinitis,

Figure 55.5 Glomerulonephritis in typhoid fever. **A**, Mesangial proliferative GN. **B**, Immunofluorescent staining demonstrates granular deposition of *Salmonella typhi* Vi antigens in the mesangium. (Courtesy V. Boonpucknavig.)

osteocondritis, and rash). In acquired syphilis, renal involvement occurs in 0.3% of all patients. Adults present with nephrotic syndrome or occasionally with an acute nephritic picture. Serologic test results for syphilis are positive (rapid plasmin reagin, VDRL, and fluorescent treponemal antibody absorption test). MN is the most common renal pathologic process, but diffuse proliferative GN with or without crescents, MPGN, and mesangial proliferative GN have also been observed. Treponemal antigens have been identified in the immune deposits. Syphilitic GN responds to antibiotic treatment, although remission may not occur for 4 to 18 months.

Acute typhoid fever from *Salmonella typhi* is characterized by fever, splenomegaly, and gastrointestinal symptoms. Severe cases may develop shock and acute renal failure as a part of disseminated intravascular coagulation or hemolytic-uremic syndrome, but these complications are rare. Overt mesangial proliferative GN occurs in 2% of the cases (Fig. 55.5), but microscopic hematuria and mild proteinuria may be present in 25% of the cases.²⁵ Diagnosis requires the culture of the organisms from blood or stools or rising antibody titers in the Widal test. GN may also occur in patients with schistosomiasis and coexisting *Salmonella* infection of the urinary tract (see Chapter 54).

Leprosy (*Mycobacterium leprae* infection) may be associated in autopsy studies with GN (5% to 14% of the cases), interstitial nephritis (4% to 54%), or amyloidosis (4% to 31%).²⁶ GN is manifested clinically in less than 2% of the patients. It remains controversial whether GN is more common in lepromatous leprosy than in tuberculoid leprosy. Urinary abnormalities consistent with GN often accompany episodes of erythema nodosum leprosum. Clinical manifestations are of nephrotic syndrome, less frequently of acute nephritic syndrome, and rarely of rapidly progressive GN. MPGN or diffuse proliferative GN with IgG,

C3, IgM, IgA, and fibrin deposits is present on biopsy. Response of glomerular disease to treatment of leprosy is variable. Amyloidosis with nephritic syndrome may also rarely occur, especially in lepromatous leprosy. Other renal abnormalities associated with leprosy include interstitial nephritis. Prednisolone (40 to 50 mg/day) has been used in short courses to treat erythema nodosum leprosum associated with GN.

Pneumococcal pneumonia may rarely be associated with microhematuria and proteinuria, especially if treatment is delayed. Both diffuse proliferative GN and mesangial proliferative GN have been reported, and pneumococcal antigen is present in the immune deposits. Rarely, pneumococcal pneumonia can also be associated with hemolytic-uremic syndrome as a result of unmasking of the Thomsen-Friedenreich antigen in glomeruli by pneumococcal neuraminidase, which then allows preformed antibodies to bind and to elicit an immune response.

Gastroenteritis due to *Campylobacter jejuni* may be associated with mesangioproliferative or diffuse proliferative GN. GN may also occur with other bacterial infections, including those with *E. coli*, *Yersinia*, meningococcus, and *Mycoplasma pneumoniae*.

VIRAL INFECTIONS

Viral infections may cause acute GN (hepatitis A virus, parvovirus B19, measles, Epstein-Barr virus), chronic GN (hepatitis B virus [HBV], hepatitis C virus [HCV], human immunodeficiency virus [HIV], parvovirus B19), and interstitial nephritis (Hantavirus, influenza virus, dengue, BK virus, coronavirus, cytomegalovirus, hepatitis A virus). The most common infections are those associated with HBV, HCV, and HIV. Pathogenetic mechanisms include deposition or *in situ* formation of exogenous (viral) immune complexes; autoantibody formation directed to endogenous antigen modified by viral injury; virus-induced release of proinflammatory cytokines, chemokines, adhesion molecules, and growth factors; and direct cytopathic effects of viral proteins.²⁷

Hepatitis A Virus–Associated Renal Disease

Renal failure associated with severe hepatitis A virus infection may be due to interstitial nephritis or acute tubular necrosis. Rarely, immune complex–related diffuse proliferative GN with immunoglobulin and C3 deposits and the clinical picture of nephritic or nephrotic syndrome may develop, at times with impaired renal function. Recovery from GN usually coincides with the improvement of hepatitis.

Hepatitis B Virus–Associated Renal Disease

HBV is a DNA virus of the Hepadnaviridae family; the human is its only known natural host. Hepatitis develops as a result of immune reactivity directed to infected hepatocytes.^{28,29}

Acute HBV infection may present with nausea, vomiting, fever, hepatomegaly, and a short-lived serum sickness–like syndrome: urticaria or maculopapular rash, neuropathy, arthralgia or arthritis, microscopic hematuria, and non-nephrotic proteinuria.²⁸ Renal biopsy, if it is performed, shows a mesangial proliferative GN. The clinical picture resolves spontaneously as the hepatitis improves.

Whereas acute HBV infection may resolve uneventfully, more than 90% of infected infants, 25% to 50% of the children infected between the ages of 1 and 5 years, and 6% to 10% of older children and adults develop chronic infection (defined as

persistence of HBsAg-positive serology but negative for IgM antibodies to HBV core antigen). Vertical (maternal-infant at birth) transmission is usually present in endemic areas, such as China and Southeast Asia. Horizontal transmission occurs through contamination with blood or direct contact with mucous membranes. In Europe and the United States, the prevalence is lower, and most carriers acquire the infection as adolescents or adults by horizontal transmission as a consequence of drug abuse, blood transfusions, or sexual relations.

HBV carriers may present with a variety of renal syndromes.

HBV-Associated Membranous Nephropathy

MN may occur in chronic HBV carriers. Children show a male predominance and often present with asymptomatic proteinuria or nephrotic syndrome, microscopic hematuria, and normal renal function, often with minimal evidence of liver disease. The prognosis is usually good, and spontaneous remission is common in association with the appearance of anti-HBe antibodies in circulation. In contrast, adults are also nephrotic but often have impaired renal function and clinically apparent liver disease and are more at risk for progression to renal failure. C3 and C4 levels are decreased in 20% to 50%. Biopsy is consistent with MN, but mesangial immune deposits may also be present, in contrast with idiopathic MN. Virus-like particles have been identified in various areas of the glomeruli. HBeAg can often be demonstrated in the immune deposits by immunohistochemistry.^{27,29}

HBV-Associated Membranoproliferative Glomerulonephritis

MPGN is the most common glomerular lesion in adult HBV carriers. Cryoglobulinemia may be present, especially if there is concurrent infection with HCV. Chronic liver disease is usually present but may be clinically asymptomatic. Nephrotic or non-nephrotic proteinuria, often associated with microhematuria, is common.²⁸ Biopsy shows typical type I MPGN, and HBsAg is occasionally shown in the immune deposits.

Mesangial Proliferative Glomerulonephritis with IgA Deposits

There are several reports of a renal lesion mimicking IgA nephropathy in HBV infection. It is possible that this is a consequence of chronic liver disease with impaired clearance of IgA circulating immune complexes, leading to hepatic IgA nephropathy (see Chapter 22).

Treatment of HBV-Associated Glomerulonephritis

Treatment is aimed at eradication of HBV virus. Interferon alfa (5 million units daily for 6 months) or pegylated interferon alfa may result in remission, especially in HBV-associated MN. Lamivudine (100 mg orally once daily for 52 weeks) has also been reported to clear HBV virus and to induce remission in HBV-associated MN. A reduction of the dose is necessary when the glomerular filtration rate (GFR) is reduced below 50 ml/min per 1.73 m². If the GFR is 30 to 49 ml/min per 1.73 m², the initial dose is 100 mg, and this is followed by 50 mg orally daily; if the GFR is 15 to 29 ml/min per 1.73 m², the initial dose is the same and subsequent doses are reduced to 25 mg daily. In patients with ESRD, the initial dose is 35 mg followed by 10 mg daily.³⁰ Lamivudine-resistant strains may arise with prolonged use. Entecavir and adefovir dipivoxil may provide an alternative, but the nephrotoxicity of adefovir is a deterrent, although the risk is low at standard dosing if renal function is normal. Corticosteroid treatment is contraindicated because it is ineffective and may

delay or prevent seroconversion and accelerate the progression of liver disease.

The prevailing view has been that treatment is not required for children with HBV-associated MN because the majority of children undergo spontaneous remission. However, clearance of HBV DNA and HBeAg has been achieved in about half of the children in controlled studies, with a higher incidence of resolution of the proteinuria in the treated group. Because HBV-associated MN may rarely progress to ESRD in children, it is reasonable to treat when proteinuria is severe or there is progression of renal disease.

Active immunization is the most effective prevention measure as shown by the 10-fold decline in the incidence in Taiwan and 67% reduction in the United States 10 years after universal vaccination was implemented in 1991.²⁷

Polyarteritis Nodosa

HBV-related vasculitis (HBV-related polyarteritis nodosa [PAN]) has become progressively rare and is observed primarily in adult men who acquire HBV infection from drug use or transfusion, usually less than 12 months after a mild attack of hepatitis. It is almost never observed in children and is rare in areas of the world where HBV infection is acquired at birth or in childhood, such as in Asia. The typical patient with HBV-related PAN presents with signs of serum sickness preceding and during a mild or asymptomatic attack of hepatitis, unlike HBV-associated serum sickness, which resolves spontaneously with clearing of the HBsAg. In these patients, the disease progresses to involve numerous organs. It typically involves medium-sized arteries and may present with a variety of presentations, including myocardial ischemia, mesenteric angina, cerebral ischemia, and mononeuritis multiplex. Renal vasculitis is manifested by microhematuria, nephrotic or non-nephrotic proteinuria, and renin-dependent hypertension. Manifestations are in general similar to those observed in noninfectious PAN, but patients with HBV-associated PAN more frequently have orchitis and gastrointestinal and renal vessel involvement, whereas pulmonary and cutaneous manifestations are rare. Rapidly progressive GN, as seen in microscopic polyangiitis, is infrequent in HBV-related PAN.³¹

The pathogenesis of HBV-associated PAN is thought to be the deposition of HBsAg-antiHBs immune complexes in the arterial wall that results in a subsequent inflammatory reaction with the activation of complement. The vessels often show a predominance of IgM and HBsAg, suggesting that the injury is mediated by HBsAg-IgM complexes. Serologic tests reveal HBsAg and anti-HBc antibodies. Serum complement is usually normal, and ANCA are absent.

Diagnosis requires detection of circulating HBsAg in association with either biopsy or angiographic evidence of vasculitis. Biopsy studies demonstrate vascular lesions, which are typically panmural and in different stages of development. Variable degrees of fibrinoid necrosis, fibrin deposition, and leukocyte infiltration are present. HBsAg, IgM, and occasionally IgG are deposited in the vessel wall. Angiographic studies demonstrating narrow segments and saccular or fusiform aneurysms in celiac or renal arteries have higher diagnostic yield than biopsies do.

Liver biopsy demonstrates chronic active or persisting hepatitis or, rarely, acute hepatitis. The renal biopsy, in addition to the arteriolar lesions, may show relatively preserved glomeruli with variable degrees of collapse in the glomerular tuft likely resulting from ischemic changes. In contrast with idiopathic microscopic polyangiitis, necrotizing lesions with crescent

formation are rare. Mesangial proliferative GN, diffuse proliferative GN, MPGN, and MN have all been reported.

Treatment consists of a short course of corticosteroids (prednisone 1 mg/kg per day for 2 weeks) and plasma exchange (9 to 12 exchanges during 3 weeks) followed by interferon alfa therapy or lamivudine.

Hepatitis C Virus–Associated Renal Disease

HCV is an RNA virus of the Flaviviridae family that is a common cause of chronic hepatitis, cirrhosis, and hepatoma. Chronic HCV infection can also be associated with the development of several types of glomerular disease.³² The most common is MPGN with or without cryoglobulinemia, and this entity is discussed in Chapter 21. HCV may also be associated with MN, especially in renal transplant patients. The clinical and histologic findings are similar to those observed in idiopathic MN except that HCV RNA and anti-HCV antibodies are present in the blood. Other reported associations include fibrillary GN, focal glomerulosclerosis (especially in African Americans), and thrombotic microangiopathy with anticardiolipin antibodies (especially after renal transplantation).³³

Human Immunodeficiency Virus–Associated Renal Disease

HIV infection may be associated with myriad renal complications, one of the most common of which is HIV-associated nephropathy. A discussion of HIV-associated nephropathy and other HIV-associated renal disorders is provided in Chapter 56.

Other Virus–Associated Renal Disease

Polymavirus nephropathy due to BK virus is increasingly recognized in renal transplantation and can be a cause of decreased renal function. It is described in detail in Chapter 101.

Cytomegalovirus (CMV) infection commonly is manifested in renal transplant recipients, in whom it can infect tubular cells and macrophages in the interstitium, resulting in the characteristic intracytoplasmic “owl-like” inclusions. Whereas there is some evidence that this may be a cause of tubular dysfunction, there is no evidence that this results in glomerular injury. Rarely, however, CMV has been reported in nontransplant subjects to cause a diffuse proliferative GN with immune deposits containing CMV antigens. In addition, a rare report has linked CMV infection with collapsing glomerulopathy and ESRD in patients not infected with HIV.³⁴

Parvovirus B19 is a single-stranded DNA virus with marked tropism for the erythroid precursor cells. In conditions in which there is increased destruction or decreased production of red cells, parvovirus infection may cause aplastic anemia as in renal transplantation and in sickle cell disease. In patients with sickle cell disease, parvovirus-induced aplastic crises are occasionally followed by nephritic or nephrotic syndrome, assumed to be the result of immune complex deposition. Diffuse proliferative GN, MPGN, and collapsing focal glomerulosclerosis (with similarities to heroin- and HIV-associated nephropathy) have been attributed to parvovirus B19 infection, and some studies but not others have detected viral DNA in kidney biopsy specimens. Granular deposition of C3 and IgG in capillary walls and subendothelial deposits have been found.³⁵ Studies have also suggested a relationship between renal parvovirus infection and chronic allograft nephropathy.³⁶

Hantavirus causes hemorrhagic fever with acute interstitial nephritis (see Chapter 66). Severe cases, occurring more frequently in endemic areas, present with acute renal failure. Milder forms are manifested with fever, hepatitis, and mild renal functional impairment. Severe acute respiratory distress syndrome caused by coronavirus may cause tubulointerstitial nephritis; acute renal failure, when it is present, is probably associated with multiorgan failure.

Many viral infections, including varicella, mumps, adenovirus, coxsackievirus, and influenza, can be associated with transient microscopic hematuria, non-nephrotic proteinuria, and a mesangial proliferative GN or diffuse proliferative GN in which viral antigens can be identified in the mesangium. Measles may also cause a diffuse proliferative GN but is better known for its unique ability to induce remission in subjects with minimal change disease with nephrotic syndrome.

Dengue hemorrhagic fever may be caused by four serotypes of the family Flaviviridae. The clinical manifestations, reflecting increased vascular permeability, include muscle pains, gastrointestinal symptoms, and, in severe cases, bleeding manifestations and shock. Acute renal failure may accompany the severe cases; in some less severely ill patients, acute endocapillary GN with mesangial proliferation may develop and may be manifested by microhematuria and proteinuria. Intense granular deposits of IgG, IgM, and C3 in mesangial areas and to a lesser degree in capillary walls are usually present.

Mild renal abnormalities can also be observed with acute Epstein-Barr virus (EBV) infection, with microhematuria and proteinuria in 10% to 15% of cases. Acute interstitial nephritis is probably the most common renal complication, but diffuse proliferative GN and MPGN may also occur. Replicating EBV was localized not only to infiltrating macrophages but also to proximal tubular cells that were shown to express the CD21 receptor for EBV. It was posited that EBV might be a major cause of chronic interstitial nephritis.²⁷

PARASITIC INFECTIONS

Kidney involvement is fairly common in different parasitic diseases. With the exception of schistosomiasis, malaria, and onchocercosis, such involvement is usually mild and transient and often masked by the manifestations of the primary disease (Fig. 55.6).

Schistosomiasis

See Chapter 54.

Malaria

Malaria, caused by the protozoan *Plasmodium*, is transmitted by *Anopheles* mosquitoes and is a major world health problem (Fig. 55.7). More than 90% of cases occur in Africa, India, Southeast Asia, and Latin America.³⁷ Malaria can also be acquired by blood transfusions,³⁸ transplantation of infected donor organs,³⁹ and bite by infected vectors introduced in aircraft (“airport malaria”).

Four major species are responsible for malaria. *P. falciparum* is usually associated with heavy parasitemia because it invades red blood cells of any age. Because all red cells can be infected, *P. falciparum* can be associated with massive infection of the red cells, resulting in acute kidney injury and multiple organ failure. This entity is discussed in more detail in Chapter 66.

Acute glomerular injury may occur with *P. falciparum* infection. Transient urinary abnormalities, such as mild proteinuria

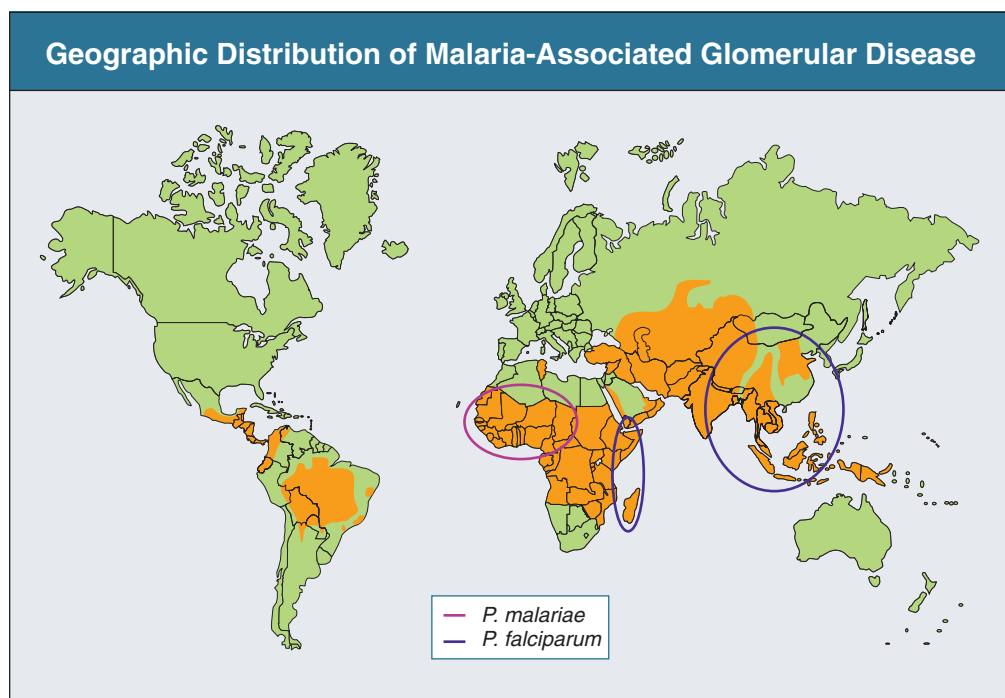

Figure 55.7 Geographic distribution of malaria-associated glomerular disease. Although malaria is endogenous to many areas of the world (shaded orange), the major areas where malaria-associated glomerular disease has been reported (ringed) and their respective species are shown.

Figure 55.8 Glomerulonephritis associated with *Plasmodium falciparum* malaria. **A**, Light microscopy shows a mesangial proliferative GN. **B**, Immunofluorescence may reveal *P. falciparum* antigens in a mesangial pattern. **C**, Peripheral blood smear confirms acute *P. falciparum* infection, with banana-shaped gametocytes and multiple ring forms in erythrocytes. (**A** reprinted with permission from reference 37; **B** and **C** courtesy of V. Boonpucknavig.)

Figure 55.9 Quartan malarial nephropathy. **A**, Light microscopy shows a sclerosing membranoproliferative glomerulonephritis. **B**, Silver stain shows a double contour of the basement membrane. **C**, Malarial antigens are present by immunofluorescence. (From reference 37.)

and microhematuria, are encountered in 25% to 50% of patients; a full-blown nephritic syndrome with hypertension, edema, and impaired renal function is uncommon.⁴⁰ Serum complement C3 and C4 may be consumed in such cases. Renal biopsy typically shows endocapillary proliferation with mesangial expansion and infiltration with pigment-laden macrophages and parasitized red cells. Platelet-fibrin thrombi and patchy necrosis of the tubules may be associated. Immunofluorescence shows granular deposition of IgM, C3, malarial antigens, and occasionally IgG.⁴¹ Dense immune complex deposits, containing plasmodial antigens, are seen by electron microscopy (Fig. 55.8).

Another malarial species, *P. malariae*, infects only aging erythrocytes and is therefore associated with a less severe form of malaria (quartan malaria). Several studies suggest that chronic quartan malaria may be associated with a corticosteroid-resistant nephrotic syndrome, referred to historically as tropical nephritis and more recently as tropical nephrotic syndrome. The disease typically affects children, usually 4 to 8 years old, and only rarely adults. It presents with heavy proteinuria and overt nephrotic syndrome, late-onset hypertension, and progressive kidney insufficiency. Despite the severe hypoproteinemia, the blood cholesterol level is often normal, presumably because of associated nutritional deficiency. Renal biopsy shows MPGN with intramembranous lacunae (due to reabsorption of immune com-

plexes). Immunofluorescence shows coarsely granular IgG, IgM, and C3 deposits, and electron microscopy displays subendothelial electron-dense deposits (Fig. 55.9). The response to corticosteroids is poor and progression to ESRD frequent, even with eradication of the malarial infection.

The identity of quartan malarial nephropathy as a specific disease, distinct from other immune complex-mediated GNs, has been challenged in recent years owing to the inconsistency of immunohistochemical evidence.⁴² It is unclear why the disease is almost restricted to Nigeria among the West African countries and Uganda in the east, being unknown in most neighboring countries where quartan malaria is endemic. However, failure to detect specific antigens in late glomerular lesions is not uncommon in most infection-related glomerulopathies, and the observation that corticosteroid-resistant nephrotic syndrome in Nigeria has significantly declined with the control of malaria is consistent with a cause-and-effect relationship.

Onchocercosis

Onchocerca volvulus is a filarial parasite, also endemic in West Africa, particularly in Cameroon, Burkina Faso, and Ghana, as well as in Central and South America, with foci in southern Arabia and Yemen. It is transmitted by a variety of

black flies of the genus *Simulium*, usually found in the vicinity of rivers.

The mature parasite lives for many years in the affected host, usually protected from the immune response by hiding in subcutaneous nodules. However, migrating microfilariae are amenable to clearance by the innate immune system, releasing antigens that provoke production of antibodies and immune complexes.

The clinical syndrome of onchocerciasis includes (1) a variety of skin manifestations, such as papular and lichenified dermatitis, hyperpigmentation or depigmentation, and atrophy; (2) chronic lymphadenopathy, forming large masses, particularly in the inguinal region; (3) obstruction of the scrotal lymphatic drainage, leading to enlargement and progressive stretching under the effect of gravity (hanging scrotum syndrome); and (4) corneal opacities and anterior uveitis caused by microfilarial invasion, respective immune-mediated inflammation, and subsequent scarring (river blindness).

Corticosteroid-resistant nephrotic syndrome with progressive impairment of renal insufficiency is the most common renal presentation. Minimal change may occur, and also mesangial proliferative GN and MPGN, often with immune complexes containing onchocercal antigens. Antifilarial treatment does not halt the disease progression because of involvement of autoimmune mechanisms. Indeed, treatment with the antifilarial drug diethylcarbamazine may exacerbate proteinuria. Onchocercal GN may recur in transplanted kidneys.⁴³

Other filarial infections, such as *Loa loa* and *Wuchereria bancrofti*, may induce mesangial proliferative GN, MN, or MPGN. Visceral leishmaniasis (kala-azar) frequently presents with microhematuria and interstitial nephritis or diffuse proliferative or membranous nephropathy. Trichinosis may also occasionally present with MPGN, manifested clinically with microhematuria and non-nephrotic proteinuria.

Human Immunodeficiency Virus Infection and the Kidney

Jeffrey Kopp, June Fabian, Saraladevi Naicker

Human immunodeficiency virus (HIV) infection is the defining infectious disease of our era. In 2009, there were an estimated 33 million infected people and 2.5 million new infections; there have been 16 million deaths since the start of the epidemic, and there are 22 available antiretroviral medications. With regard to nephrologic issues, HIV-1 infection is associated with glomerular and tubulointerstitial disease, and patients with HIV infection are also at risk for nephrotoxicity from antiretroviral therapy (ART) as well as from other medications. Coinfections with other pathogens, in particular hepatitis B and hepatitis C viruses, can complicate the clinical picture. Acute kidney injury (AKI) and interstitial nephritis, due to medication and opportunistic infection, are not uncommon. As patients with HIV disease live longer with ART, patients are experiencing the complex, interacting effects of HIV infection itself, ART, and the worldwide diseases of development, including atherosclerosis, metabolic syndrome, type 2 diabetes, and end-stage renal disease (ESRD). Patients with HIV disease and chronic kidney disease (CKD) and ESRD, those receiving chronic dialysis therapy, and those undergoing kidney transplantation face particular issues and concerns.

In addition to HIV-1, HIV-2 can cause immunodeficiency but rarely causes kidney disease. In this chapter, we use HIV to stand for HIV-1.

HIV-ASSOCIATED KIDNEY DISEASE

General Approach

The evaluation of a patient with acute or chronic kidney disease in the setting of HIV infection resembles that in other settings: history, focused particularly on medication use and other infections; physical examination; examination of the urine sediment; serum and urine chemistries; and, in many cases, renal imaging studies. Urine chemistries may include 24-hour timed or spot urine measurement of protein and albumin (for suspected glomerular disease), glucose, phosphate, and uric acid (for suspected proximal tubular disease). Indications for kidney biopsy include AKI without clear associated cause, especially with a nephritic sediment; nephrotic proteinuria; clinical evidence of thrombotic microangiopathy; and unexplained CKD. In the past, some clinicians have argued that nephrotic proteinuria in an individual of African descent is likely to be HIV-associated collapsing glomerulopathy and that a biopsy is superfluous. Whether that once may have been true, the evolution of kidney diseases during the past decade with the widespread use of ART has rendered that judgment increasingly problematic, and it now appears more prudent to define the histologic features to guide prognosis and therapy.

GLOMERULAR DISORDERS

HIV-Associated Collapsing Glomerulopathy

HIV infection is associated with a number of glomerular disorders (Fig. 56.1). The classic glomerulopathy of HIV infection is collapsing glomerulopathy (CG). The pathologic changes were described in early reports as focal segmental glomerulosclerosis (FSGS) and more recently as HIV-associated nephropathy, but this latter term has also been used to describe other glomerular pathologic processes associated with HIV infection.

Etiology and Pathogenesis

There has been steady progress in deciphering how HIV infection results in injury to glomerular and tubular cells. HIV-associated CG occurs in both acute infection and chronic infection; in the latter case, it is associated with higher viral RNA levels and lower CD4 T-lymphocyte counts. It appears that HIV can infect glomerular and tubular cells, setting up a chronic and possibly latent infection.¹ There is also evidence that particular HIV accessory proteins damage renal cells, independent of direct infection. First, in transgenic mice, the expression of HIV-1 accessory protein Vpr or Nef in podocytes are associated with progressive CKD, leading to ESRD, loss of podocyte differentiation markers, and features suggestive of human CG and segmental glomerulosclerosis. Transgenic mouse experiments also suggest that HIV-1 gene products are toxic to tubular epithelial cells, resulting in apoptosis and a cytokinetic block. Second, Vpr and Nef proteins are toxic to cultured renal cells.

Host factors play a major role in determining susceptibility to HIV-associated CG. Individuals of African descent have a striking predilection for HIV-associated CG, with relative risk compared to individuals of European descent of approximately 20-fold. This predilection was originally identified as a consequence of variation in *MYH9*, encoding myosin heavy chain 9, a component of non-muscle myosin IIA. The *MYH9* risk haplotype contributes to risk for idiopathic FSGS (odds ratio 4) and HIV-associated CG (odds ratio 6). More recently, much of the risk attributed to *MYH9* genetic variation has been shown to more closely associate with coding-region polymorphisms in *APOL1* (encoding apolipoprotein L1), which is in close linkage disequilibrium with *MYH9* polymorphisms. Apolipoprotein L1 is a constituent of high density lipoprotein. It remains unknown whether these *APOL1* polymorphisms cause chronic kidney disease, and by what molecular mechanism. Nevertheless, homozygosity or dual heterozygosity for two risk alleles (labeled G1 and G2) are observed in 50% of African Americans with HIV-associated CG, compared to only 12% of African American control subjects. Interestingly, these variants appear to protect

Kidney Diseases Associated with HIV Infection			
Entity	Frequency	Associations	
Glomerular	Collapsing glomerulopathy	Common	African descent; particularly advanced HIV disease
	Immune complex glomerulonephritis	Common	European, Asian descent, and black Africans in Africa
	Thrombotic microangiopathy	Uncommon	
	Membranoproliferative glomerulonephritis, with or without cryoglobulin-associated vasculitis	Rare*	Hepatitis C; enfuvirtide
	Membranous nephropathy	Rare*	Hepatitis B
	Fibrillary and immunotactoid glomerulopathies	Rare*	
	Amyloid nephropathy (AA type)	Rare*	
	Minimal change nephropathy	Rare*	Non-steroidal anti-inflammatory medication
Tubular	Acute kidney injury	Moderately common	Aminoglycosides, cidofovir, foscarnet
	Proximal tubule injury (Fanconi syndrome)	Moderately common	Tenofovir, adefovir, cidofovir, didanosine
	Diabetes insipidus	Uncommon	Amphotericin, tenofovir, didanosine, abacavir
	Chronic tubular injury	Moderately common	Amphotericin, cidofovir, adefovir, tenofovir
	Crystal nephropathy	Uncommon	Indinavir, atazanavir; sulfadiazine, ciprofloxacin, intravenous acyclovir
Interstitial	Interstitial nephritis	Uncommon	Allergy to beta-lactam, sulfa, ciprofloxacin, rifampin, proton pump inhibitor, allopurinol, phenytoin; also causes of crystal nephropathy listed above BK virus; generally advanced disease Immune reconstitution inflammatory syndrome; generally advanced disease; following initiation of ART

Figure 56.1 Kidney diseases associated with HIV infection. Shown are diseases that are associated with HIV infection or its treatment. *Certain glomerular diseases are commonly associated with other viral infections or may occur on an idiopathic basis; a true association with HIV disease is uncertain or doubtful. Collapsing glomerulopathy is notable for glomerular, tubular, and interstitial disease but is classified under glomerular disease for simplicity. ART, antiretroviral therapy.

individuals from African sleeping sickness due to *Trypanosoma brucei rhodesiense*, and this may explain apparently rapid spread of these alleles in certain African populations that has occurred during the past 10,000 years.^{2,3}

Clinical Manifestations

Patients with HIV-associated CG typically present with laboratory abnormalities, including proteinuria and renal insufficiency; some patients present with edema, although edema is less common than with other nephrotic conditions or with uremia. Imaging studies may reveal increased kidney size despite reduced glomerular filtration rate (GFR) and, in some cases, increased echogenicity; this unusual feature is shared with diabetic nephropathy and amyloid nephropathy. However, no radiologic features predict the renal histology, and renal biopsy is required for diagnosis.

Pathology

On histologic examination, HIV-associated CG is virtually indistinguishable from idiopathic CG and is a pan-nephropathy, with pathologic changes in the glomeruli (proliferation and dysregulation of podocytes or podocyte stem cells, together with glomerular collapse), tubules (acute and chronic injury,

sometimes with microcystic tubular changes), and interstitium (chronic inflammation, fibrosis) (Fig. 56.2). Both HIV-associated CG and idiopathic CG may manifest tubuloreticular inclusions within dilated endosomal compartments within glomerular endothelial cells, which is believed to be a marker for cytokine (interferon) injury. Some pathologists make the diagnosis of classic FSGS in the setting of HIV infection, and others see this rarely; it is unclear whether these differences are due to population differences or to different diagnostic standards in distinguishing FSGS from CG. It may also be that in a patient with progressive loss of kidney function (e.g., from hypertensive nephrosclerosis or interstitial nephritis), the consequent glomerular hyperperfusion and hyperfiltration lead to glomerulomegaly and postadaptive FSGS.

Diagnosis and Differential Diagnosis

The diagnosis of glomerular disease is made by renal biopsy showing classic changes of HIV-associated CG. Among individuals of African descent, nephrotic proteinuria and low CD4 count suggest the diagnosis of HIV-associated CG; plasma HIV RNA of less than 400 copies/ml suggests that another disease is more likely. Potential diagnoses include hypertensive nephrosclerosis, diabetic nephropathy, and HIV-related immune

Figure 56.2 HIV-associated collapsing glomerulopathy. Typical histology in HIV-associated collapsing glomerulopathy (CG), often termed HIV-associated nephropathy. **A**, A globally collapsed glomerulus shows marked podocyte hypertrophy and hyperplasia (Jones methenamine silver). **B**, At low power, the renal parenchyma contains abundant tubular microcysts with proteinaceous casts. The glomerulus is collapsed with dilated urinary space (periodic acid–Schiff). **C**, The glomerular endothelial cell pictured here contains a large intracytoplasmic tubuloreticular inclusion (“interferon footprint”; arrow) composed of interanastomosing tubular structures within a dilated cisterna of endoplasmic reticulum (electron micrograph).

complex glomerulonephritis (ICGN) (see later discussion and Fig. 56.1).

Treatment

Current treatment guidelines suggest that the diagnosis of HIV-associated nephropathy is an indication for the initiation of ART

in patients who are not currently receiving these medications and is not influenced by T-lymphocyte count.⁴ It would seem reasonable to extend this recommendation to HIV-associated ICGN, but there are no systematic data that address this point.

There are several lines of evidence supporting a recommendation to use ART. In patients who are not receiving ART, the course of disease progression in HIV-associated CG may be fast, with patients reaching ESRD in months to a few years. By contrast, epidemiologic data (the decline in HIV-associated ESRD in the United States after the introduction of ART in 1995) suggest that effective control of viral replication with ART can prevent the appearance of HIV-associated CG. Retrospective studies suggest that the institution of ART after the diagnosis of HIV-associated CG may prolong renal survival.⁵ A Ugandan study has demonstrated improvement of kidney function after 2 years of ART, but long-term outcomes are awaited.⁶ Progression of CKD is more rapid in HIV-infected individuals of African descent, probably reflecting a racial predilection.⁷ This is of particular relevance to the African population in sub-Saharan Africa that has the highest prevalence rates of HIV infection. Further support for screening has come from observations that ART improves renal outcome, preferably when it is initiated before the onset of severe renal disease^{8–10}; the approach to CKD screening is discussed later. There are isolated case reports of improvement of renal function and, in some cases, regression of histologic lesions with ART.^{10,11} For ethical reasons, a randomized control trial of this hypothesis has not and will not be undertaken.

Treatment of HIV-associated renal disease includes general and specific measures. Standard therapies for CKD are likely to be effective, including control of blood pressure to below 130/80 mm Hg and the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs). Non-randomized studies suggest benefit from these interventions, but randomized controlled studies have not been performed. Nonetheless, treatment guidelines prepared by the panel brought together by the National Institutes of Health suggest that one indication for initiation of ART is HIV-associated CG.¹² Several nonrandomized studies have suggested a benefit from corticosteroid therapy, but because the efficacy appears to be modest and often short-lived, this is not considered standard therapy.

HIV-Associated Immune Complex Glomerulonephritis

In populations of European and Asian ancestry, the most common glomerular disease associated with HIV disease is immune complex glomerulonephritis (ICGN); this is true among developed countries (e.g., European Union) and developing countries (e.g., Thailand). Importantly, HIV-associated ICGN is also seen in populations of African descent.¹³ The pathogenesis of HIV-associated ICGN is not well understood. In some cases, immune complexes have been shown to include HIV antigen. It may be that other cases are due to the general polyclonal B-cell expansion that accompanies HIV disease. Clinically, these patients typically present with nephrotic proteinuria and hematuria and thus may be clinically indistinguishable from those with HIV-associated CG. On histologic examination, the glomeruli show diffuse or focal proliferative glomerulonephritis (GN) with endocapillary proliferation. In some cases, changes consistent with HIV-associated CG may also be present. Immune deposits are characterized by IgG and IgM or by IgG, IgM, and IgA (so-called full house deposits), often with C3. These forms

resemble lupus nephritis, although lupus serologic test results are typically negative. Patients who have coinfection with hepatitis C virus (HCV) may manifest membranoproliferative glomerulonephritis (MPGN), with double glomerular capillary basement membrane contours. Other patients may have only IgA deposits, in the setting of microscopic hematuria and (typically) subnephrotic proteinuria, resembling idiopathic IgA nephropathy. The long-term outcome of HIV-associated ICGN has not been well defined but in general is believed to be relatively benign in most cases. There are few studies of therapy; presumably, control of HIV infection and conservative measures to control blood pressure and proteinuria are indicated.

TUBULAR DISORDERS

HIV infection is associated with a number of tubular disorders, many of which are secondary to various drugs commonly used in this disease (see Fig. 56.1).¹⁴ AKI, as defined by the AIDS Clinical Trials Group, occurs with a creatinine concentration below 1.5 mg/dl or an increase of 1.3-fold that resolves within 3 months.¹⁵ Most HIV-associated AKI occurs outside hospitals; major causes include prerenal impairment, postrenal impairment (including obstruction due to prostate disease, kidney stone, or crystalluria), medication toxicity (including interstitial nephritis due to antibiotics or indinavir, tubular injury due to tenofovir or other agents, and statin-associated rhabdomyolysis), and less commonly acute presentations of glomerular diseases. Risk factors reported in one or more cohorts have included male sex, black race, low CD4 count, high viral load, diabetes, CKD, and hepatic disease.¹⁶

Proximal tubular injury is moderately common, manifested as various combinations of glycosuria, phosphaturia (sometimes associated with clinically significant hypophosphatemia), uricosuria, proteinuria, and aminoaciduria. Diabetes insipidus may also be present, indicating that the distal nephron is also involved. The most common cause is tenofovir, which is taken up by proximal tubular cells by one or more organic anion transporters and is believed to impair mitochondrial function and also to inhibit DNA repair or replication. A mild decrease in GFR has also been associated with tenofovir use, but it was not severe enough for treatment to be discontinued.¹⁷ Whereas three controlled studies have suggested minimal nephrotoxicity (perhaps 1%) when tenofovir is used for periods up to 48 weeks, a growing number of case series suggest that some patients manifest tubular injury that resolves during a period of months to years.¹⁸ This apparent incongruity may be explained by the use of tenofovir in clinical practice in patients with other renal injury risk factors and by its frequent long-term use. Risk factors for tenofovir-induced renal toxicity include prior renal impairment and possibly combined therapy with didanosine.

Other protease inhibitors are also associated with variable risk for nephrotoxicity (Fig. 56.3). Nucleotide and nucleoside reverse transcriptase inhibitors (NRTIs) are associated with variable effects on tubular function. Besides the renal effects with tenofovir, the most common renal toxicities are seen with indinavir, which is associated with crystalluria, nephrolithiasis, or AKI (see Fig. 56.3). Although there have been cases of AKI, most of these case reports have been associated with multiple compounding factors (sepsis, concomitant nephrotoxic agents), and most are reversible.¹⁷ Lopinavir and ritonavir may increase plasma

Renal Toxicity of Antiviral Therapy			
Antiretroviral Class	Antiretroviral Therapy	Renal Effect	Clinical Recommendations
Protease Inhibitors	Indinavir	Nephrolithiasis, crystalluria, dysuria, papillary necrosis, acute kidney injury, interstitial nephritis Ritonavir and lopinavir may increase toxicity of indinavir	Daily fluid intake of >2 l/day
	Ritonavir	Reversible AKI (usually in combination with nephrotoxic drugs)	
	Saquinavir, nelfinavir	Renal calculi (rare)	Increased fluid intake
Reverse Transcriptase Inhibitors	Tenofovir, abacavir	Renal tubular damage: proximal tubular dysfunction, Fanconi syndrome, nephrogenic diabetes insipidus, acute tubular necrosis, AKI	Patients taking tenofovir should be monitored for signs of tubular dysfunction (elevated serum creatinine, hypophosphatemia, low serum uric acid, acidosis glycosuria, proteinuria)
	Didanosine, lamivudine, stavudine	Isolated case reports of tubular dysfunction	
Other	Cidofovir, adefovir	Renal tubular damage, proximal tubular dysfunction (cidofovir)	

Figure 56.3 Renal toxicity of antiviral therapy. The toxicity of these agents has been the subject of a recent review. (From reference 17.)

concentrations of tenofovir by 30%. NRTIs have a good renal safety profile.¹⁷ Non-nucleoside reverse transcriptase inhibitors (NNRTIs) also have a good safety profile, with an isolated case report of AKI from interstitial nephritis due to a hypersensitivity reaction to efavirenz. The fusion inhibitor enfuvirtide has been associated with an isolated case report of MPGN in a diabetic patient.

CHRONIC KIDNEY DISEASE AND END-STAGE RENAL DISEASE IN THE PATIENT WITH HIV INFECTION

Epidemiology

The Developed World

Since the advent of highly active ART in 1996, increasing numbers of patients with HIV disease are receiving therapy, dramatically increasing the life span of patients and turning the disease into a chronic condition. This has been associated with an evolution in the pattern of renal disease. Early in the epidemic, the leading renal diagnoses included HIV-associated CG in individuals of African descent and ICGN associated with either IgA or all immunoglobulins in other individuals. In recent years, the range of common diagnoses has expanded to include diabetic nephropathy (DN) and hypertensive nephrosclerosis. In those with hepatitis, membranous nephropathy (MN) associated with hepatitis B and MPGN associated with hepatitis C should be considered. Uncommon but important diagnoses include MN (presumably idiopathic, but possibly related to the polyclonal B-cell expansion typical of HIV disease) and amyloid. Chronic tubular injury, especially associated with tenofovir therapy but possibly associated with other ART, is not uncommon; but when early diagnosis leads to cessation of the offending medication, CKD is usually averted. Despite the plethora of diagnoses, HIV-associated CG remains the leading cause of ESRD in patients with HIV disease.

The incidence of HIV-associated ESRD, typically not histologically examined by the United States Renal Data System, has remained relatively constant in the United States during the past decade, but the prevalence has risen because of increased survival of patients on dialysis. During the period 1995 to 2000, the number of *prevalent* ESRD cases in HIV-seropositive individuals rose by 159%, accounting for 1.2% of prevalent ESRD patients (this includes all individuals in the United States receiving dialysis or with a functioning renal allograft). In 2000, among *incident* ESRD cases, 851 (0.88%) were attributed to HIV-associated kidney disease, and another 320 cases (0.33%) were in HIV-seropositive individuals but attributed to other causes (the accuracy of the assessment of the cause of ESRD is unknown, as kidney biopsies may not be performed). In 2006, the annual incidence rate of ESRD attributed to HIV-associated renal disease for individuals of African descent, adjusted for age and sex, was 22 cases/million compared with 0.35 case/million among individuals of European descent, representing a relative risk of 63.¹⁹ During the same period, first-year mortality for HIV-associated ESRD patients starting ESRD therapy, unadjusted for age, was 32%, which is higher than for ESRD patients as a group (24%). The prevalence rates are quite similar in France, where 0.6% of ESRD cases were HIV-positive during the period 2002 to 2004. Compared with the U.S. data, individuals had a more favorable 2-year patient survival rate of 89%, similar to that of other ESRD patients.²⁰

The Developing World

More than two thirds of the total HIV-infected population in the world live in sub-Saharan Africa, and the majority infected are women (61%). Within the region, southern Africa is the worst affected, with the national adult HIV prevalence exceeding 15% in eight southern African countries from 2005. Transmission of HIV infection is largely heterosexual contact in most of the region. Only 30% of HIV-infected individuals have access to ART in Africa. Sub-Saharan Africa has a dearth of data describing the impact of HIV infection on the kidney, and renal histologic studies are scant. Access to renal replacement therapy (RRT) is also frequently limited. Reported prevalence of CKD has been assessed by the presence of albuminuria or (eGFR) (based on serum creatinine measurements) and ranges widely from 6% to 45%. This wide variation may be partly ascribed to differences in study design, populations studied, and definitions used for CKD based on dipstick proteinuria and quantitative measure of proteinuria or serum creatinine.

In terms of etiology, some studies have shown HIV-associated CG to be present in more than 80% of kidney biopsy specimens, which is consistent with findings in the United States, but others show a broader spectrum of disease, including ICGN due to postinfectious and other causes, MN and interstitial nephritis. There are nonspecific histologic changes, such as mesangial hyperplasia and chronic active interstitial nephritis, that do not necessarily fulfill the diagnostic criteria for HIV-associated CG but show regression on ART, which suggests that the histologic criteria for HIV-associated CKD may need to be revised.²¹⁻²³

A significant response of HIV-associated CKD to ART has been shown, with the median eGFR improving by 21% after 2 years on ART.⁶ The presence of kidney dysfunction, in the setting of HIV infection, acts as an independent predictor of poor outcome, with an increased mortality after 90 days.²⁴

There are few data on the worldwide prevalence of CKD in HIV infection. In a cross-sectional study from 31 European countries, Israel, and Argentina, CKD (defined as an eGFR of ≤ 60 ml/min per 1.73 m^2) was present in 4.7% of HIV-infected subjects by use of the Modification of Diet in Renal Disease (MDRD) formula. A study from Hong Kong showed CKD (defined as eGFR ≤ 60 ml/min per 1.73 m^2 or proteinuria for more than 3 months) in 18% of HIV-infected Chinese patients, but this study excluded those with ESRD. Isolated screening studies with relatively small numbers using persistent proteinuria as a marker of CKD have been done in various countries with the following prevalence rates: 1.1% to 5.6% in Brazil, 18% in Switzerland, 27% in India, and 20% in Iran.

Dosing of Antiretroviral Therapy in Chronic Kidney Disease

Many antiretroviral medications are partially or completely eliminated by the kidney and require dose adjustment in CKD (Fig. 56.4). Certain drug classes, such as the protease inhibitors and the NNRTIs, are extensively metabolized by the liver and do not require dose adjustment.²⁵ Most of the NRTIs are excreted unchanged in the urine and require dose adjustment, with the exception of zidovudine and abacavir, which both have substantial extrarenal biotransformation that requires less or no dose adjustment. In uremia, drug dosing may be affected by altered gastric pH and variable volumes of distribution.²⁶ Factors that influence dialyzability of antiretroviral medications relate to the properties of the dialysis membrane and molecular weight,

Dose Adjustments for ART in CKD and ESRD		
Name	CKD (adjusted according to creatinine clearance or by eGFR)	Dialysis
Nucleoside or nucleotide analogues		
Abacavir	No adjustment	No adjustment HD: dosing independent of dialysis sessions
Azidothymidine (AZT), zidovudine ^a	CrCl \geq 15 ml/min: no adjustment CrCl <15 ml/min: 100 mg PO q6-8h	HD: 100 mg PO q6-8h ^a or 300 mg PO qd PD: no data

Figure 56.4 Dose adjustments for ART in CKD and ESRD. FDA recommendations are based on CrCl or eGFR calculated as ml/min, but are likely valid for these expressed as ml/min per 1.73 m². Atripla (efavirenz, tenofovir, and emtricitabine is not recommended for CrCl < 5 ml/min. CrCl, creatinine clearance; HD, hemodialysis; PD, peritoneal dialysis.

degree of protein binding, molecular charge, and water solubility of the drug. If removal of the drug occurs during hemodialysis (HD), it should be taken after dialysis. If the drug is removed in peritoneal dialysis (PD) effluent, the dose may have to be supplemented.²⁶ Dosing recommendations in both HD and PD are limited by the lack of reliable data. Fixed drug combinations should not be used in patients with eGFR below 30 to 50 ml/min.²⁵

RENAL REPLACEMENT THERAPY IN THE PATIENT WITH HIV INFECTION

With the increasing survival of HIV-infected patients with treatment and the declining cost of ART, the magnitude of HIV-associated ESRD will likely increase worldwide, as it has in developed countries.²⁷ Life expectancy in HIV infection with ART has increased by 10 to 20 years in developed countries, and many of these patients are now dying of the complications of ESRD rather than of HIV infection. Currently, HIV-infected subjects requiring either HD or PD, who are stable on ART, are achieving survival rates comparable to those of dialysis patients without HIV infection, and choice of dialysis modality does not have an impact on survival.

Immunization schedules are the same as for non-HIV-infected dialysis patients and should include vaccinations for *Streptococcus pneumoniae*, influenza virus, hepatitis A, and hepatitis B.¹⁵ In both CKD and HIV infection, the presence of anemia is independently associated with shorter survival. The response to recombinant erythropoietin (EPO) in HIV-infected patients with ESRD was similar to that in HIV-negative patients.²⁸ Measurements of iron indices are complicated in HIV-infected patients, especially as levels of ferritin are often elevated in patients with HIV infection.

Hemodialysis

Strict use of universal precautions is the best form of prevention of HIV transmission in dialysis units. HIV-infected patients do not have to be isolated from other patients or dialyzed on separate machines. Reprocessing of dialyzers from HIV-positive patients should not place staff members at increased risk for infection if necessary sterile precautions are undertaken. The risk of HIV seroconversion after a needle stick injury from an infected patient is estimated to be about 0.3%. Art may reduce the risk of transmission following a needle-stick injury and should be considered under certain circumstances, as recommended by the Centers for Disease Control and Prevention. Native arteriovenous fistulas are the preferred types of access because of excellent patency once established and lower complication rates compared with those associated with other access options.

Peritoneal Dialysis

HIV has been shown to survive in peritoneal effluents at room temperature for up to 7 days and in PD exchange tubing for up to 48 hours. Dialysate should therefore be handled as a contaminated body fluid.²⁹ Sodium hypochlorite (50% solution) and household bleach (10% solution), each further diluted 1:512, are effective at killing HIV in dialysate. PD patients should be instructed to pour dialysate into the home toilet and to dispose of dialysate bags and lines by tying them in plastic bags and disposing of the plastic bags in conventional home garbage.^{15,30}

Kidney Transplantation

Kidney transplantation has been performed with success in HIV-infected patients. Preliminary short-term data in liver, kidney, and heart transplant recipients suggest that patient survival rates are similar to those of HIV-uninfected transplant recipients, and there has been no increase in the prevalence of opportunistic infection.³¹ In spite of high rates of acute graft rejection, survival appears to be similar to that of HIV-uninfected recipients. In areas with high endemic rates of HIV infection, it has been proposed that HIV-infected cadaveric donor organs may be transplanted into HIV-infected recipients with ESRD.³² Four such transplantations have been performed with good graft and recipient survival, but the data are preliminary.

SCREENING FOR CHRONIC KIDNEY DISEASE

As noted before, treatment of HIV-associated CG, and possibly HIV-associated ICGN, may slow progression of renal functional decline. Limited studies suggest that creatinine clearance and the eGFR equation provide suitable estimates of true GFR. Microalbuminuria may indicate early glomerular disease (diabetes, hypertensive nephrosclerosis, HIV-associated glomerular disease), tubular disease (drug toxicity), metabolic syndrome, or systemic inflammation. Its role in diagnosis and screening in the setting of HIV infection remains to be determined.

Patients with HIV disease are at increased risk for CKD and should receive regular screening. A committee of the Infectious Diseases Society of America has laid out a proposal for screening.¹⁵ Support for screening has come from published data confirming that CKD in HIV infection is common, can occur at any stage of HIV infection (even before seroconversion), and can progress rapidly to ESRD if it is untreated.

The role of microalbuminuria in the natural history of HIV-associated CKD and screening is an area of active investigation. Microalbuminuria is associated with an increased risk of cardiovascular disease and mortality in certain well-defined high-risk settings, such as diabetes and hypertension. Han and colleagues²¹ found that six of seven South African patients with persistent microalbuminuria had HIV-associated CG; these findings tell us that HIV-associated CG can present insidiously, at a stage when therapy may slow its progression. Nevertheless, these patients were ART naïve, and this HIV-infected population may lack the high prevalence of diabetes, hypertension, and drug-induced renal toxicity that characterizes patients with HIV disease in developed countries. Szczech and colleagues³³ found microalbuminuria in 11% of patients with HIV disease compared with 2% of control subjects; the presence of microalbuminuria was associated with insulin resistance, systolic hypertension, and advanced HIV disease characterized by a low CD4 count. Whether this association predicts increased risk of cardiovascular disease and mortality in HIV disease needs to be investigated.

Screening, early detection, and treatment of HIV-associated CKD are strongly recommended (Fig. 56.5). In the algorithm, management of leukocyturia, in addition to proteinuria, has been included as it occurs commonly and the presence of sterile pyuria may be associated with comorbid disease. Urinary screening is inexpensive and easy to perform and to interpret, provided guidelines are given to staff at the primary health care level to initiate treatment, to investigate, and, if necessary, to refer. Effective screening programs are more realistic in resource-limited developing countries when the alternative is

Figure 56.5 Management algorithm for screening of HIV-infected antiretroviral therapy-naïve patients for chronic kidney disease.

Tuberculosis may be pulmonary or extrapulmonary. ACE, angiotensin-converting enzyme; ARB, angiotensin II receptor blocker; ART, antiretroviral therapy; CKD, chronic kidney disease; eGFR, estimated glomerular filtration rate, calculated by the Cockcroft-Gault formula or the modified MDRD formula; STI, sexually transmitted infection; UTI, urinary tract infection. Antiproteinuric agents may be used in normotensive individuals with gradual up-titration of dose, depending on tolerance and severity of proteinuria.

Management Algorithm for Screening of HIV-Infected Antiretroviral Therapy-Naïve Patients for Chronic Kidney Disease

Assessment for kidney disease in all HIV-infected individuals at presentation.

Risk factors: race, family history of CKD, use of nephrotoxic agents (including traditional medicines), diabetes mellitus, hepatitis C, HIV viral load >4000 copies/ml, CD4 count <200 cells/mm³.

Investigations: urine dipstick and serum creatinine, calculate eGFR (see Chapter 3).

Urine dipstick for leukocytes.

If leukocytes or nitrites present: urine microscopy and culture.

UTI symptoms: treat empirically; adjust treatment according to culture results if indicated.

Sterile pyuria: exclude STI (including syphilis) and tuberculosis

Repeat urine dipstick at follow-up visit.

Urine dipstick for proteinuria

If negative, test for microalbuminuria (see Chapters 29 and 76). If no proteinuria or microalbuminuria, repeat screen in 12 months in those at risk for development of CKD.

Proteinuria or microalbuminuria: exclude potential causes of proteinuria: fever, infection (UTI, STI, tuberculosis), pregnancy, uncontrolled diabetes, uncontrolled hypertension, cardiac failure.

Treat comorbid conditions: repeat urine dipstick in 1 month.

If nephrotic, nephritic, or nephritic/nephrotic: refer for investigation and management.

Start ART.

At follow-up: In patients with persistent proteinuria (random protein/creatinine ratio ≥ 2 g/g) or MDRD eGFR <60 ml/min per 1.73 m², investigate with kidney ultrasound, serologic testing for hepatitis C and B, *Plasmodium malariae* (if appropriate, depending on infections endemic to the region), autoimmune screen. In patients with persistent microalbuminuria (random albumin/creatinine 17–250 mg/g in men, 25–355 mg/g in women), it is prudent to consider whether diabetic nephropathy might be present (an indication for ACE or ARB) and in other patients, to evaluate regularly for the appearance of macroproteinuria or reduced GFR.

Refer to a nephrologist, if available.

If unable to refer: ART: adjust dose according to eGFR.

If still proteinuric after 3 months on ART: start antiproteinuric agents (see Chapter 76).

K⁺ <5.0 mmol/l: ACE inhibitor or ARB and check K⁺ in 1 week.

K⁺ >5.0 mmol/l: potassium-binding resin or use of nondihydropyridine calcium channel blocker: verapamil or diltiazem.

Manage stage of CKD appropriately (see Chapter 76).

considered, which is that access to RRT is extremely limited and progression of CKD to ESRD is ultimately fatal for most patients.

Nephrolithiasis and Nephrocalcinosis

Rebeca D. Monk, David A. Bushinsky

Kidney stones are common and are associated with significant morbidity. Nephrolithiasis refers to stone formation within the renal tubules or collecting system, although calculi are often found within the ureters or in the bladder. Most renal calculi are calcium oxalate, calcium phosphate, struvite, urate, and cystine. Clinical presentation varies from asymptomatic small stones to large, obstructing staghorn calculi that impair renal function and cause chronic kidney disease. The severity of stone disease depends on the pathogenesis as well as on the stone type, size, and location. Nephrolithiasis classically presents as ureteral colic but may also commonly present with hematuria or urinary tract infection (UTI). Diffuse renal parenchymal calcification is termed nephrocalcinosis. The calcifications are usually calcium phosphate or calcium oxalate and may be deposited in the renal cortex or medulla, depending on etiology.

NEPHROLITHIASIS

Epidemiology

Kidney stones are common in industrialized nations, with an annual incidence of more than 1 per 1000 persons and a lifetime risk of forming stones of 5% to 13%.¹⁻³ In the United States, the prevalence of nephrolithiasis has increased from 3.2% in the late 1970s to 5.2% in the 1990s,⁴ in parallel with the rising incidence of obesity, insulin resistance, and type 2 diabetes mellitus.^{5,6} Incidence peaks in the third and fourth decades and prevalence increases with age until approximately 70 years in men and 60 years in women.⁷ Factors that determine renal stone prevalence include age, sex, race, and geographic distribution. In the United States, Caucasians are more likely to develop renal stones than are African Americans, Hispanics, or Asian Americans. Men are more prone to stone formation than are women, at a ratio of 2 to 4:1. In the United States, the tendency for the development of stones also depends on geographic location, with an increasing prevalence from north to south and, to a lesser degree, from west to east. The increase in nephrolithiasis rates in the American Southeast may be due to the greater sunlight exposure, leading to an increase in insensible losses through sweating and more concentrated urine.^{2,8} The higher urine calcium excretion in a smaller urine volume will increase the risk for supersaturation for calcium, thereby promoting stone formation.

Stone type varies with worldwide geography and genetic predisposition. In the Mediterranean and Middle East, 75% of stones are composed of uric acid; whereas in the United States, the majority of stones are calcium oxalate or calcium phosphate (>70%), with less than 10% pure uric acid stones. Magnesium ammonium phosphate (struvite) stones account for 10% to

25% of stones formed (with a higher incidence in the United Kingdom), and cystine stones represent 2% of all stones formed (Fig. 57.1).^{7,9,10}

Outbreaks of kidney stones can also be due to dietary supplements or medications. Recently, a large number of Chinese infants and toddlers developed kidney stones and, in some cases, renal failure due to obstructive stones. The outbreak was associated with melamine contamination in infant formulas and powdered milk as a means of raising the apparent concentration of protein in the products.¹¹⁻¹³

Pathogenesis

Stones occur in urine that is supersaturated with respect to the ionic constituents of the specific stone. Supersaturation is dependent on the product of the free ion activities of stone components rather than on their molar concentrations. Whereas an increasing concentration of crystal components increases their free ion activity, other factors diminish it. When calcium and oxalate are dissolved in pure water, for example, the solution becomes saturated when the addition of any more calcium or oxalate does not result in further dissolution. However, urine, unlike pure water, contains numerous ions and molecules that can form soluble complexes with the ionic components of a stone. The interactions with these other solutes (e.g., citrate) may result in a decrease in free ion activity, which allows the stone constituents to increase in total concentration to levels that would normally cause stone formation in water. Urinary pH also influences free ion activity. The level of chemical free ion activity in which stones will neither grow nor dissolve is referred to as the equilibrium solubility product, or the upper limit of metastability. Above this level, the urine will be supersaturated, and any stone present will grow in size.

When the solution becomes supersaturated with respect to a solid phase, ions can join together to form the more stable, solid phase, a process termed nucleation. Homogeneous nucleation refers to the joining of similar ions into crystals. The more common and thermodynamically favored heterogeneous nucleation results when crystals grow around dissimilar crystals or other substances in the urine, such as sloughed epithelial cells. Calcium oxalate crystals, for example, can nucleate around uric acid crystals. For stones to grow sufficiently large in size to obstruct before being excreted in the urine, several small crystals generally bond together rapidly in a process termed aggregation.

Crystals then grow into a clinically significant calculus by anchoring to the renal epithelium. Calcium oxalate crystals anchor on areas of calcium phosphate deposits termed Randall's

Figure 57.1 Proportion of stone types in a typical U.S. population.

Clinical Presentations of Nephrolithiasis	
Presentation	Characteristics
Pain	Ureteral colic, loin pain, dysuria
Hematuria	—
Urinary tract infection	Recurrent, chronic infection; pyelonephritis
Asymptomatic urine abnormality	Microscopic hematuria, proteinuria, sterile pyuria
Interruption of urinary stream	—
Calculus anuria	—

Figure 57.2 Clinical presentations of nephrolithiasis.

plaques, which are located in the renal papillae and composed of apatite crystals. The apatite appears to originate around the thin loop of Henle, in the tubular basement membrane, and extends into the interstitium without filling the tubular lumen or damaging the tubular cells. Calcium oxalate crystals attach to these plaques, allowing significant stone growth.¹⁴⁻¹⁶

Clinical Manifestations

The two most characteristic symptoms of nephrolithiasis are pain and hematuria. Other presentations include UTI and acute kidney injury due to obstructive uropathy if stones cause bilateral renal tract obstruction or unilateral obstruction in a single functioning kidney (Fig. 57.2).

Pain

The classic presentation of pain in patients with nephrolithiasis is ureteral colic. Pain is of abrupt onset and intensifies over time into an excruciating, severe flank pain that resolves only with stone passage or removal. The pain may migrate anteriorly along the abdomen and inferiorly to the groin, testicles, or labia majora as the stone moves toward the ureterovesical junction. Gross hematuria, urinary urgency, frequency, nausea, and vomiting may occur. Stones smaller than 5 mm usually pass spontaneously with hydration, whereas larger stones often require urologic intervention (Fig. 57.3).^{15,17} Ureteral colic may also occur with the passage of clots from hematuria of any cause (“clot colic”) or with papillary necrosis. As well as colic, nephrolithiasis may provoke less specific loin pain that poorly localizes to the kidney

Figure 57.3 Ureteral calculus. A 1-cm-wide calcium oxalate stone that provoked ureteral colic and required surgical removal.

Causes of Hematuria
Nephrolithiasis
Infection: cystitis, prostatitis, urethritis, acute pyelonephritis, tuberculosis, schistosomiasis
Malignancy: renal cell carcinoma, transitional cell carcinoma, prostatic carcinoma, Wilms' tumor
Trauma
Glomerular disease
Interstitial nephritis
Polycystic kidney disease
Papillary necrosis
Medullary sponge kidney
Coagulopathy: bleeding disorders, anticoagulation therapy
Miscellaneous: loin pain hematuria syndrome, arteriovenous malformation, chemical cystitis, caruncle, factitious

Figure 57.4 Causes of hematuria.

and therefore has a wide differential diagnosis, particularly if it is not associated with other urinary symptoms. The finding of a stone on radiologic examination does not preclude a coincidental cause of pain from another etiology.

Hematuria

Stone disease is a common cause of hematuria. Macroscopic hematuria occurs more commonly with large calculi and during UTI and colic. Although it is typically associated with loin pain or ureteral colic, the hematuria of nephrolithiasis may also be painless. The clinical differential of hematuria is therefore wide (Fig. 57.4). Painless microscopic hematuria in children may occur with hypercalciuria in the absence of demonstrable stones.

Loin Pain–Hematuria Syndrome

Loin pain–hematuria syndrome is a poorly understood condition that must always be considered in the differential diagnosis of nephrolithiasis. It is diagnosed by exclusion when patients (most typically young and middle-aged women) present with loin pain and persistent microscopic or intermittent macroscopic hematuria.¹⁸ Careful evaluation is required to exclude small stones, tumor, UTI, and glomerular disease. Angiographic abnormalities implying intrarenal vasospasm or occlusion have been reported, as have renal biopsy abnormalities typified by deposi-

tion of complement C3 in arteriolar walls. However, these findings are not consistent, nor do they provide a coherent framework to explain the pathogenesis of this condition.

In one study, 43 consecutive patients with clinical manifestations of loin pain–hematuria syndrome were evaluated by renal biopsy after other causes of their symptoms were excluded with at least two imaging studies.¹⁹ Thirty-four subjects were considered to have idiopathic loin pain–hematuria syndrome after nine with histologic evidence of IgA nephropathy were excluded. Of these, 66% had glomerular basement membranes that were either unusually thick or thin on electron microscopy, and 47% had a history of kidney stones, although none had obstructing stones at the time of assessment. Evidence of glomerular hematuria was more common in biopsy specimens of patients with loin pain–hematuria syndrome compared with those of healthy living kidney donors who also underwent renal biopsy. The investigators postulated that the structurally abnormal glomerular basement membranes in the majority of these patients may lead to rupture of the glomerular capillary walls, with consequent hemorrhage into the renal tubules. Tubular obstruction by red blood cells or potentially by microcrystals ensues. Local and global renal parenchymal edema follows, ultimately resulting in stretching of the renal capsule and severe flank pain.

Loin pain–hematuria syndrome is a chronic condition requiring reassurance, careful management of analgesia, and ongoing psychological support. The condition usually remits after several years. Denervation of the kidney by autotransplantation is rarely successful.²⁰ The extreme measure of nephrectomy has been used, but pain often recurs promptly in the contralateral kidney. Bilateral nephrectomy with renal replacement therapy has been reported as an approach of very last resort. Referral to a pain clinic can assist in providing psychiatric counseling, analgesia, and exclusion of other disorders. In one retrospective study, patients who eventually came to accept a nonsurgical approach along with pain-coping strategies that did not involve narcotic analgesics had the most successful outcomes.²¹

Asymptomatic Stone Disease

Even large staghorn calculi may be asymptomatic and discovered during the investigation of unrelated abdominal or musculoskeletal symptoms. Obstructive uropathy caused by calculi may also be painless; therefore, nephrolithiasis should always be considered in the differential diagnosis of unexplained renal failure.

In the recent outbreak of melamine-associated nephrolithiasis in Chinese infants, the majority presenting to a screening clinic had no symptoms or signs of stones. The diagnosis of nephrolithiasis was made by ultrasound in at-risk infants and toddlers.¹³

Clinical Evaluation of Stone Formers

All patients with recurrent nephrolithiasis merit metabolic evaluation to determine the cause of their kidney stones. Complete evaluation of patients with a single stone is controversial because of the undetermined cost-benefit ratio. A National Institutes of Health Consensus Development Conference on the Prevention and Treatment of Kidney Stones determined that all patients, even those with a single stone, should undergo a basic evaluation, which need not include a 24-hour urine collection. Those with metabolically active stones (stones growing in size or number within 1 year), all children, non–calcium stone formers, and patients in demographic groups not typically prone to stone formation warrant a more complete evaluation that includes

Basic Evaluation of Nephrolithiasis

Stone history
 Number of stones formed
 Frequency of stone formation
 Age at first onset
 Size of stones passed or still present
 Kidney involved (left, right, or both)
 Stone type, if known
 Need for urologic intervention: ESWL, percutaneous nephrolithotomy, etc.
 Response to surgical procedure
 Are stones associated with urinary tract infections?

Medical history

Medications

Family history

Occupation, lifestyle

Fluid intake, diet

Physical examination

Evidence of systemic causes of stones (e.g., tophi)

Laboratory data

Urinalysis
 Urine culture
 Stone analysis

Blood chemistry

Sodium, potassium, chloride, bicarbonate
 Creatinine, calcium, phosphorus, uric acid
 Intact parathyroid hormone level if calcium elevated

Radiologic evaluation

KUB
 Helical CT
 IVU
 Ultrasound

Figure 57.5 Basic evaluation of nephrolithiasis. CT, computed tomography; ESWL, extracorporeal shock wave lithotripsy; IVU intravenous urography; KUB, kidneys, ureters, bladder.

a 24-hour urine collection made with the patient taking the typical diet.²²

Basic Evaluation

Clinic evaluation of stone formers includes a general history and physical examination. Specific data gathering on stone formation and the diet and specific laboratory studies are required, as shown in Figure 57.5.

History History serves to uncover a systemic etiology for nephrolithiasis. Any disease that can lead to hypercalcemia (including malignant neoplasm, hyperparathyroidism, and sarcoidosis) can result in hypercalciuria and increase the risk for calcium stone formation. A number of malabsorptive gastrointestinal disorders (including Crohn's disease and sprue [celiac disease]) can result in calcium oxalate stone formation as a result of volume depletion and hyperoxaluria. Uric acid stones often occur in patients with a history of gout and increasingly in patients with insulin resistance.¹⁰

Stone history (see Fig. 57.5) includes the number and frequency of stones formed, the age of the patient at occurrence of the first stone, the size of stones, the stone type (if known), and whether the patient required surgical removal of the calculi. This information indicates the severity of the stone disease and provides clues to the etiology of the stone formation. For

example, large staghorn calculi that do not pass spontaneously and recur despite frequent surgical intervention are more consistent with struvite than with calcium oxalate stones. Stones that develop at a young age may be caused by cystinuria or primary hyperoxaluria. Stone response to intervention is also significant; cystine stones, for example, do not fragment well with lithotripsy. If stones recur frequently in a single kidney, a congenital abnormality in that kidney, such as megacalyx or medullary sponge kidney, should be explored.

Family history is important because a number of stone types have a genetic basis. Idiopathic hypercalciuria is most likely a polygenic disorder; cystinuria is usually autosomal recessive; and hyperuricosuria has been associated with rare inherited metabolic disorders. Nephrolithiasis and nephrocalcinosis can also result from a variety of monogenic disorders, such as Dent disease (X-linked recessive nephrolithiasis), McCune-Albright syndrome, osteogenesis imperfecta type I, and congenital lactate deficiency. The various genetic disorders can lead to hypercalciuria by their effect on increasing either bone resorption or intestinal absorption, by decreasing renal tubular reabsorption transport, or through other as yet unknown mechanisms.^{2,15,16,23,24}

A number of medications are known to potentiate calcium stone formation (e.g., loop diuretics are calciuric) or may predispose to uric acid lithiasis (salicylates, probenecid) (Fig. 57.6). Certain drugs can precipitate into stones themselves, such as rapidly infused intravenous acyclovir, high-dose sulfadiazine, triamterene, and the antiretroviral agents indinavir and nelfinavir.²⁵

Medications Associated with Nephrolithiasis and Nephrocalcinosis	
Calcium Stone Formation	
Loop diuretics	
Vitamin D	
Corticosteroids	
Calcium supplements	
Antacids (calcium and noncalcium antacids)	
Theophylline	
Acetazolamide*	
Amphotericin B*	
Uric Acid Stone Formation	
Salicylates	
Probenecid	
Allopurinol (usually associated with xanthine stones)	
Melamine (in contaminated infant formula and milk products)	
Medications That May Precipitate into Stones	
Triamterene	
Acyclovir (if infused rapidly intravenously)	
Indinavir	
Nelfinavir	

Figure 57.6 Medications associated with nephrolithiasis and nephrocalcinosis. *Associated with nephrocalcinosis.

Social history should include details about occupation and lifestyle. Cardiothoracic surgeons and real-estate agents, for example, may minimize fluid intake to avoid bathroom breaks during the workday. Those who engage in vigorous physical activities, such as running, may not rehydrate adequately to keep up with insensible losses, producing excessively concentrated urine and precipitation of stone crystals in those prone to nephrolithiasis.

Dietary history and review of fluid intake are essential in determining potential causes of or contributors to stone formation. The patient should be asked about commonly consumed foods, with attention paid to sodium-containing foods as well as quantities of calcium, animal protein, purine, and oxalate (Fig. 57.7). Dietary calcium intake should be reviewed as many patients with nephrolithiasis are erroneously instructed to eliminate all calcium from their diet, a suggestion that can result not only in bone demineralization, particularly in women and children, but also in an increase in stone formation.^{3,26-29}

Physical Examination Most patients with idiopathic hypercalciuria are healthy and have normal physical examination

Foods High in Oxalate and Purine	
High Oxalate Foods (avoid in setting of hyperoxaluria)	
Green beans	
Beets	
Celery	
Green onions	
Leeks	
Leafy greens: collard greens, dandelion greens, Swiss chard, spinach, escarole, mustard greens, sorrel, kale, rhubarb	
Cocoa	
Chocolate	
Black tea	
Berries: blackberries, blueberries, strawberries, raspberries, currants, gooseberries	
Orange peel	
Lemon peel	
Dried figs	
Summer squash	
Nuts, peanut butter	
Tofu (bean curd)	
High Purine Foods (avoid in setting of hyperuricosuria)	
Organ meats: sweetbreads, liver, kidney, brains, heart	
Shellfish	
Meat: beef, pork, lamb, poultry	
Fish: anchovies, sardines (canned), herring, mackerel, cod, halibut, tuna, carp	
Meat extracts: bouillon, broth, consommé, stock	
Gravies	
Certain vegetables: asparagus, cauliflower, peas, spinach, mushrooms, lima and kidney beans, lentils	

Figure 57.7 Foods high in oxalate and purine.

findings. In contrast, subjects with hyperuricosuria and uric acid stone formation may display tophi. Central obesity is associated with a predisposition to metabolic syndrome and uric acid stones. Similarly, paraplegic subjects with chronic indwelling bladder catheters may be predisposed to chronic UTI and struvite stones.

Laboratory Findings Urine pH is generally high in patients with struvite and calcium phosphate stones but low in patients with uric acid and calcium oxalate stones. The specific gravity, if it is high, will confirm inadequate fluid intake in many patients. Hematuria may imply active stone disease with crystal or stone passage. Examination of the urine may reveal red blood cells along with characteristic crystals (Fig. 57.8). Bacteriuria with urine pH above 6 to 6.5 suggests struvite stones. Urine should be cultured, and because many bacteria produce urease even when urine bacterial colony counts are low, the microbiology laboratory should be instructed to type the organism even if there are fewer than 100,000 colony-forming units/ml.

Blood tests required in the basic evaluation are serum electrolytes (sodium, potassium, chloride, and bicarbonate), creatinine, calcium, phosphorus, and uric acid. If the serum calcium concentration is elevated or at the upper limit of normal, especially if the serum phosphorus concentration is low, a serum parathyroid hormone level should be measured. A low potassium or bicarbonate level may indicate a cause of hypocitraturia, such as distal renal tubular acidosis.

Stone Analysis Patients should be encouraged to retrieve any stone they excrete for chemical analysis, which may define the underlying metabolic abnormality and guide therapy.

Imaging Patients should have a plain film of the abdomen performed with views of the kidneys, ureters, and bladder (KUB). This will reveal opacifications in the areas of the kidneys and ureters that could be due to calcium, cystine, or struvite stones (Fig. 57.9). Uric acid and xanthine calculi are radiolucent and will not be visible on plain films. The unenhanced helical computed tomography (CT) scan, also known as spiral CT or CT urography (Fig. 57.10), has replaced contrast-enhanced intravenous urography (IVU) as the diagnostic test of choice for acute ureteral colic; it has a higher sensitivity and specificity than IVU for detection of ureteral stones and ureteral obstruction¹⁷ and avoids the need for administration of contrast material. CT urography is more likely to reveal causes of colic other than stones. It is more rapid, with results being available in minutes rather than hours, an advantage in the emergency department setting. However, an experienced radiologist, required for optimal interpretation of the images, may not be available at all times in urgent care facilities. Disadvantages of CT imaging include a radiation dose approximately three times that of conventional IVU and higher cost. Both tests should be avoided or limited in patients at risk for radiation exposure, such as children and pregnant women.³⁰⁻³⁴

Contrast material should generally be avoided in patients with renal impairment or other contraindications to the use of contrast agents. The IVU generally demonstrates urinary tract obstruction caused by calculi (Fig. 57.11) and can identify abnormalities of the genitourinary tract that may predispose to stone formation, such as medullary sponge kidney (see Chapter 45) and calyceal anomalies (see Chapter 50). During acute colic, the radiographic contrast material used in the IVU, by creating a strong osmotic diuresis, may assist in moving the stone along the ureter.

Figure 57.9 Radiopaque renal calculi. **A**, X-ray examination showing multiple cystine stones in the right kidney, right ureter, and bladder. **B**, Struvite stones: left staghorn calculus and a single bladder stone.

Renal ultrasound provides great specificity in the evaluation of stones but is not a sensitive screening test. Both radiolucent and radiopaque stones within the kidneys should be detectable on ultrasound, but ureteral stones are often missed. Nonetheless, this is the test of choice for those patients who must avoid radiation exposure.

If stones are radiopaque, a KUB film can be obtained if a patient develops symptoms suggestive of recurrent stone disease. Periodic monitoring, if it is deemed necessary, should be obtained with a KUB film rather than with CT, whenever possible, to minimize radiation exposure.

Figure 57.10 Stone in the right renal pelvis. Helical (spiral) CT scan showing a single stone in the right renal pelvis. There is no hydronephrosis. (From www.gehealthcare.com/user/ct/products/urologyimagegallery.html.)

Figure 57.11 Obstructive uropathy resulting from nephrolithiasis in a patient with acute renal impairment. **A**, X-ray examination showing a stone in the right upper ureter and a very small stone in the lower left ureter (arrows). **B**, Intravenous urography at the same time showing bilateral hydronephrosis caused by ureteral obstruction. Opacification of the right ureter ends at the site of the stone (arrow).

Optimal 24-Hour Urine Values in Recurrent Nephrolithiasis	
Urine Values in 24 Hours	
Volume	>2–2.5 l
Calcium	<4 mg/kg (0.1 mmol/kg), ~300 mg (7.5 mmol) in men, ~250 mg (6.3 mmol) in women
Oxalate	<40 mg (0.36 mmol)
Uric acid	<750 mg (4.5 mmol) in women, <800 mg (4.7 mmol) in men (can be pH dependent)
Citrate	>320 mg (17 mmol)
Sodium	<3000 mg (<130 mmol)
Phosphorus	<1100 mg (35 mmol)
Creatinine	>10 mg/kg (88 μ mol/kg) in women and >15 mg/kg (132 μ mol/kg) in men, if specimen is a complete collection
Urine Supersaturation Values*	
Calcium oxalate supersaturation	<5
Calcium phosphate supersaturation	0.5–2
Uric acid supersaturation	0–1

Figure 57.12 Evaluation of nephrolithiasis: optimal 24-hour urine values. *The ratio between the actual ion activity product and its solubility product.

The Complete Evaluation

A complete evaluation should be undertaken in patients with multiple or metabolically active stones (i.e., stones that grow in size or increase in number within a year), in all children, in demographic groups not typically prone to stone formation, and in those with stones other than those containing calcium.

In addition to the basic evaluation, the complete evaluation includes a 24-hour urine collection for quantification of supersaturation for calcium oxalate, brushite (calcium phosphate), and uric acid (Fig. 57.12). Urine for supersaturation analysis has been shown to correlate well with stone composition.³⁵ Patients can bring their specimens to a local laboratory or may directly mail them to specialized laboratories that measure calcium, oxalate, citrate, uric acid, creatinine, sodium, potassium, magnesium, sulfate, phosphorus, chloride, urine urea nitrogen, and pH. Supersaturation is calculated for calcium oxalate, calcium phosphate, and uric acid by use of a software program such as EQUIL2.^{36,37} Calculation of supersaturation from a 24-hour urine collection will provide values lower than the peak postprandial supersaturation that may initiate stone formation. Only an undersaturated urine ensures that stones will not recur; the risk of stone formation rises with increasing supersaturation.

JESS (Joint Expert Speciation System) is a different program that measures the concentration of the various complexes in solution under many different conditions. It may prove to be more accurate than supersaturation analysis but is currently used for research purposes only.^{38,39} In the absence of supersaturation analysis, most laboratories assess urine volume and the quantity of calcium, oxalate, phosphorus, uric acid, sodium, citrate, and creatinine excreted in a 24-hour urine collection (see Fig. 57.12).

Urine creatinine is useful in assessing adequacy of the collection; men should excrete more than 15 mg/kg (132 μ mol/kg) and women should excrete more than 10 mg/kg (88 μ mol/kg) daily. A disadvantage of the standard 24-hour urine collection is that laboratories vary in the preservatives required to process the various constituents. Many require more than one collection to measure all the urinary constituents, reducing compliance and therefore the accuracy of the results. Determination of supersaturation is far more informative than evaluation of the individual urinary constituents.

Patients should be encouraged to perform the urine collection on a typical day while eating a typical diet, although many patients prefer to collect the urine at weekends, when their diet and habits may differ from those on usual workdays. Specialized testing, such as the use of diets high or low in calcium, is not recommended.²² Careful instructions should be given to avoid overcollection or undercollection.

General Treatment

Intervention for stone removal may be required when pain, obstruction, and infection due to nephrolithiasis do not respond to conservative management. Surgical management of stones includes extracorporeal shock wave lithotripsy and both endoscopic and percutaneous surgical removal of stones (see Chapter 59). The risk for development of renal impairment varies with types of stone, and this must be considered in planning management.⁴⁰

Medical Management

Patients who are seen by stone “specialists” often have a decrease in stone recurrence even without pharmacologic intervention.⁴¹ This phenomenon, termed the stone clinic effect, is probably due to modifications in diet and fluid intake. These nonpharmacologic measures include an increase in fluid intake, which increases urine volume; restriction of dietary sodium, which leads to a reduction of urine calcium excretion; restriction of animal protein, which also leads to a reduction of urine calcium excretion and an increase in excretion of the calcification inhibitor citrate; and ingestion of an age- and gender-appropriate amount of dietary calcium. Although dietary calcium restriction continues to be prescribed by many physicians, increasing evidence indicates that this is not beneficial and can actually increase the rate of stone formation (see later, Calcium Stones).^{3,27,42}

Fluid Intake An increase in urine volume to more than 2 to 2.5 liters daily has been proven to reduce the incidence of stones.^{41,43,44} Large urine volumes will reduce calcium oxalate supersaturation as well as precipitation of other crystals. Increased fluid intake to augment urine volume is also a mainstay of therapy for patients with uric acid and cystine stones. The period of maximum risk for stone formation is at night, when urine concentration is physiologically increased. Patients should be encouraged to drink enough fluid in the evening to provoke nocturia and then drink more fluid before returning to bed.

Salt Intake Urine sodium excretion augments urine calcium excretion.⁴⁵ Conversely, dietary salt restriction is associated with a decrease in calcium excretion. Patients should be instructed to limit daily sodium intake to 2 g (87 mmol sodium).

Dietary Protein Animal protein ingestion increases the frequency of renal stone formation by a number of mechanisms.

Metabolism of certain amino acids leads to generation of sulfate ions, which render urinary calcium ions less soluble.^{46,47} The metabolic acidosis that results from protein ingestion causes calcium release from bone and a consequent increase in the filtered load of calcium.^{46,47} Acidosis also decreases tubular calcium reabsorption, resulting in hypercalciuria. Urinary citrate excretion is also pH dependent, with acidosis leading to a decrease in citrate excretion. The result of increased animal protein intake is therefore an increase in urinary calcium ions that are rendered less soluble because of concomitant sulfate excretion and hypocitraturia. Low urine pH, coupled with increased uric acid excretion from the metabolism of animal protein, can result in uric acid lithiasis. For these reasons, stone formers should consume only a moderate-protein diet (0.8 to 1.0 g/kg daily).⁷ Dietary fructose may also increase uric acid lithiasis.⁴⁸

Dietary Calcium Despite conventional wisdom, studies have demonstrated a decrease in stone incidence when people consume diets adequate in calcium.^{44,49-51} This beneficial effect has been attributed to the binding of ingested oxalate (which is highly lithogenic) by the additional dietary calcium. Whereas women have reduced stone formation on a higher calcium diet, an exception may be in those taking calcium supplements.⁵² Some have postulated that this increased risk may be due to timing of the supplement calcium ingestion apart from meals, which would enhance calcium absorption without reducing oxalate absorption.

Previously, hypercalciuric patients were divided into those with excessive renal calcium excretion ("renal leak") and those who absorbed excessive amounts of calcium through the gastrointestinal tract ("absorptive hypercalciuria"). However, studies have shown that hypercalciuric patients generally do not have a transport defect limited to a single site. In both hypercalciuric rats and humans prescribed a low-calcium diet, there is a continuous, wide spectrum of calcium excretion, with many subjects excreting more calcium than they consume. This negative calcium balance must be derived from demineralization of bone, by far the largest repository of calcium in the body.^{26,28,53} Support for the use of an age- and gender-appropriate amount of dietary calcium was provided by a randomized prospective study comparing the rate of stone formation in men assigned to a low-calcium diet with that in men assigned to a normal-calcium, low-sodium, and low-animal protein diet.²⁷ The men assigned to the low-calcium diet were twice as likely to have recurrent stones during 5 years compared with those on the normal-calcium, low-sodium, and low-animal protein diet. Urinary calcium oxalate supersaturation also diminished more rapidly in those on the higher calcium diet and remained lower than that of men on the low-calcium diet for most of the 5-year study. This reduction in supersaturation was due to a greater fall in urinary oxalate in the men eating the normal-calcium, low-sodium, and low-animal protein diet.^{27,54}

Patients prescribed low-calcium diets can avoid excessive hyperoxaluria when they are adequately instructed to consume a low-oxalate diet.⁵⁵ Some experts contend that this approach may benefit patients with excessive intestinal absorption of calcium associated with severe hypercalciuria by allowing calcium restriction without risk of significant osteopenia.

We recommend, however, an age- and gender-appropriate calcium diet, although "excessive" dietary calcium intake and calcium supplements should be avoided in patients with calcium nephrolithiasis. Because stone formation can be reduced with normal calcium intake and there is a risk of bone demineraliza-

tion with calcium restriction, we consider the low-calcium diet obsolete.^{27,28,54}

SPECIFIC TYPES OF STONES

Calcium Stones

Calcium-containing kidney stones represent approximately 70% of all stones formed. Most calcium stones are composed of calcium oxalate, either alone or in combination with calcium phosphate or urate. A small percentage of stones are composed entirely of calcium phosphate.⁷ Most calcium stones do not exceed 1 to 2 cm in width, although surgical intervention is often required for stones larger than 5 mm.

Calcium stones may develop as a result of excessive excretion of calcium (hypercalciuria), oxalate (hyperoxaluria), and uric acid (hyperuricosuria); insufficient citrate excretion (hypocitraturia); renal tubular acidosis; certain medications; and congenital abnormalities of the genitourinary tract (Fig. 57.13). Specific therapy for patients with calcium stones depends on the underlying metabolic abnormalities detected on evaluation. Nonspecific or general therapy as outlined before should always be instituted; however, more definitive treatment is often required.

Hypercalciuria

Etiology Hypercalciuria with no other demonstrable metabolic abnormality is termed idiopathic hypercalciuria. These patients typically have excessive intestinal calcium absorption and may also have decreased renal tubular calcium reabsorption and decreased bone mineralization. The etiology of this systemic disorder in calcium transport has, in hypercalciuric stone-forming rats and in humans, been linked to an excessive number of receptors for vitamin D.⁵⁶ Metabolic disorders leading to an elevation in serum calcium, parathyroid hormone, or 1,25(OH)₂D₃ also may result in hypercalciuria.

Treatment For hypercalciuria, the usual first-line therapy is a thiazide diuretic, which acts to reduce urinary calcium. In the United States, chlorthalidone (25 to 50 mg) is the drug of choice as it requires only once-daily administration. Indapamide (1.25 to 2.5 mg daily) does not tend to raise serum lipids as much as other thiazides do and may be preferred for patients with cardiac risk factors or elevated serum lipids. On commencing these medications, patients should be instructed to increase their dietary potassium intake, and a serum potassium level should be checked 7 to 10 days later. If the level is low, oral potassium supplementation should be initiated. Potassium citrate is preferred to potassium chloride as citrate forms complexes with urinary calcium, further lowering supersaturation. However, most patients find potassium citrate liquid preparations unpalatable. A wax matrix tablet is well tolerated and is available in some countries. In general, patients are able to maintain a normal serum potassium level with 20 to 40 mmol of potassium citrate daily. The serum potassium and bicarbonate levels should be rechecked 7 to 10 days later for further dose adjustment. As citrate is a base, potassium citrate may excessively raise the serum bicarbonate level or urinary pH, and a change to potassium chloride may be required. The 24-hour urine calcium, sodium, and citrate excretion should be rechecked after several weeks. If the calcium excretion remains elevated, the thiazide dose should be increased. If the sodium excretion also remains high, patients should be encouraged to limit their sodium intake further as they will not have an adequate response to the diuretic on a

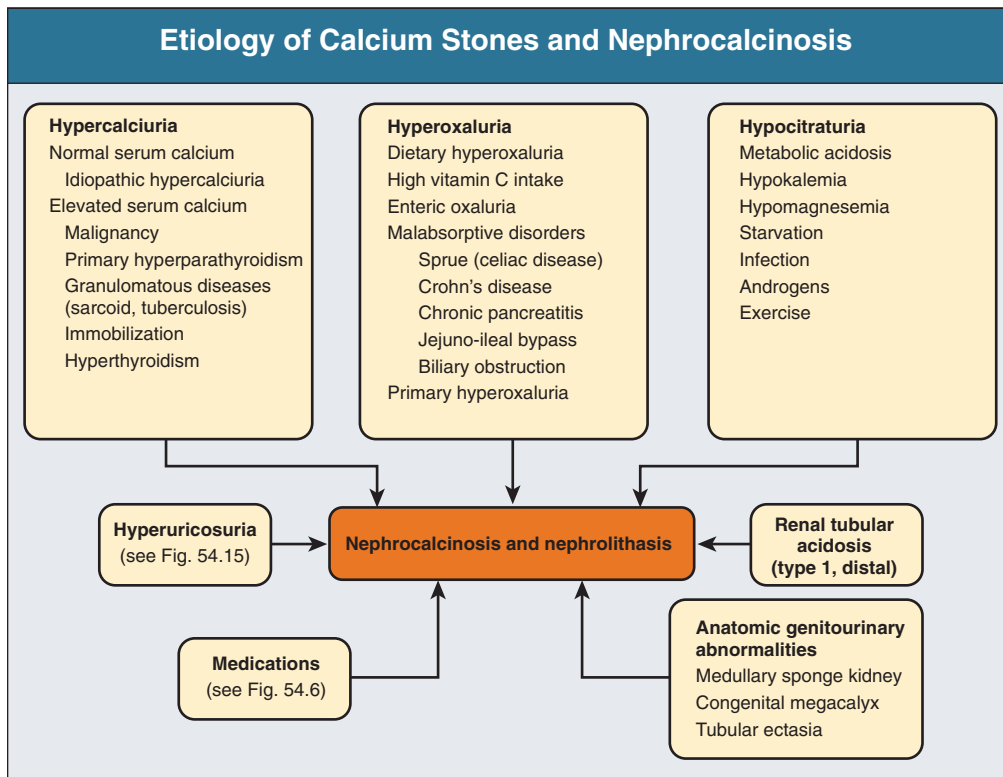

Figure 57.13 Etiology of calcium stones and nephrocalcinosis.

high-sodium diet. If the serum potassium remains low despite supplementation or the calcium excretion remains high despite increased thiazide dosing, addition of a potassium-sparing diuretic may be required to increase serum potassium. Triamterene itself can precipitate into stones; therefore, amiloride (starting dose, 5 mg daily) or a combination tablet that includes both a thiazide and amiloride should be added.^{7,57,58}

Dietary Recommendations See General Treatment.

Hyperoxaluria

Etiology Elevated urinary oxalate results from excessive dietary intake (dietary oxaluria), gastrointestinal disorders that can lead to malabsorption (enteric oxaluria), or an inherited enzyme deficiency that results in excessive metabolism of oxalate (primary hyperoxaluria) (see Fig. 57.13).⁵⁹

Dietary excess of oxalate generally does not raise urinary oxalate above 60 mg/24 h (0.54 mmol/24 h). Enteric oxaluria may occur when malabsorption results in excessive colonic absorption of oxalate due to sprue (celiac disease), Crohn's disease, chronic pancreatitis, or short bowel syndrome or after bariatric surgery. The anion exchange transporter Slc26a6 appears responsible for intestinal oxalate secretion, and mice with targeted inactivation of this transporter have hyperoxaluria.⁶⁰ It is not yet known whether patients with enteric hyperoxaluria have mutations in Slc26a6. Urinary oxalate is generally more than 60 mg/24 h and can exceed 100 mg/24 h (0.54 and 0.9 mmol/24 h).⁶¹ In primary hyperoxaluria, the tremendous oxalate production results in widespread calcium oxalate deposition throughout the body at an early age. This infiltration of calcium oxalate into organs can result in cardiomyopathy, bone marrow suppression, and renal failure. Urinary oxalate values may range from 80 to 300 mg/24 h (0.72 to 2.70 mmol/24 h).

There are two types of primary hyperoxaluria with unique enzymatic defects in the liver glyoxylate pathway.⁶² In type I, the defective enzyme is alanine-glyoxylate aminotransferase, encoded by the gene *AGXT* on chromosome 2. Type II tends to be a milder disorder and is caused by mutations in the *GRHPR* gene on chromosome 9, which results in failure of glyoxylate reduction to glycolate.^{15,59,62}

Treatment of Dietary and Enteric Hyperoxaluria Treatment of dietary oxaluria consists of dietary oxalate restriction. Patients should be given a list of foods that have high oxalate content to be avoided or to be eaten in moderation (see Fig. 57.7). Calcium carbonate (1 to 1.5 g) may be added at each meal and snack to bind intestinal oxalate and to prevent its absorption.

Specific therapy for the malabsorptive disorder, such as a gluten-free diet for patients with sprue, is the first line of treatment of enteric hyperoxaluria. More generalized therapy for steatorrhea, such as a low-fat diet, cholestyramine, and administration of medium-chain triglycerides, may reduce fat malabsorption as well as oxalate absorption and subsequent excretion. The low-oxalate diet and mealtime calcium carbonate prescribed for patients with dietary oxaluria are also helpful for these patients. The diarrhea associated with these disorders may result in low urine volumes, hypokalemia, hypocitraturia, and hypomagnesuria. Patients should therefore be advised to increase their fluid intake and to take potassium citrate (in this case, the liquid, although unpalatable, is better absorbed than the tablets) as well as a magnesium supplement. Magnesium also serves as a urinary stone inhibitor and can be given as magnesium gluconate (0.5 to 1 g every 8 hours) or magnesium oxide (400 mg every 12 hours).

Treatment of Primary Hyperoxaluria Primary hyperoxaluria is a severe disorder that can be cured only with liver transplanta-

tion to replace the defective hepatic enzyme. Pyridoxine (vitamin B₆ in doses ranging from 2.5 to 15 mg/kg per 24 hours) may reduce oxalate production in patients with type I primary hyperoxaluria. Efforts should be made to render the calcium and oxalate more soluble in the urine by raising the urinary pH (to at least 6.5) and giving supplemental citrate and magnesium. Potassium citrate and magnesium supplementation can be prescribed as before. Orthophosphate is also an effective inhibitor of urinary calcium oxalate precipitation and can be safely administered in patients with a glomerular filtration rate (GFR) above 50 ml/min. As oxalate is poorly excreted in chronic kidney disease and is not removed well by dialysis, renal transplantation serves not only to improve renal function but also to improve oxalate excretion and to diminish systemic oxalosis.^{15,63}

Oxalobacter formigenes primarily uses oxalate for cellular metabolism.^{64,65} Calcium oxalate stone formers who are colonized with *O. formigenes* have lower urine oxalate levels than do those who are not colonized.⁶⁴ A small human therapeutic trial of administration of *O. formigenes* resulted in a modest decrease in urinary oxalate in some.⁶⁵ Whether this novel approach to reducing urinary oxalate will become accepted therapy is not yet clear.

Hypocitraturia

Citrate inhibits stone formation. A number of conditions reduce urinary citrate excretion, predisposing to stone formation. Excessive protein intake, hypokalemia, metabolic acidosis, exercise, hypomagnesemia, infections, androgens, starvation, and acetazolamide have all been implicated in decreased urinary citrate excretion. Therapy involves treatment of the underlying condition and potassium citrate supplementation. The potassium salt is preferred to sodium citrate as sodium promotes renal calcium excretion. Potassium citrate (15 to 25 mmol two or three times daily) is required, and tablets are considered by most patients to be more palatable than the liquid preparation. In patients with renal impairment, serum potassium concentration should be monitored, and dose reduction may be needed if hyperkalemia develops.^{7,15,66}

Distal Renal Tubular Acidosis

Patients with distal (type 1) renal tubular acidosis have impaired distal tubular excretion of hydrogen ions with a non-anion gap metabolic acidosis and an alkaline urine (see Chapter 12). The acidosis causes calcium and phosphate to be released from bone with an ensuing increase in renal excretion of these ions. The acidosis also leads to an increase in citrate reabsorption by the proximal tubule. The end result is a high urinary pH, hypocitraturia (urinary citrate generally <100 mg/24 h [0.53 mmol/24 h]), and increased renal excretion of calcium and phosphate, all of which increase the propensity for calcium phosphate precipitation. Nephrocalcinosis in this setting is not uncommon. The metabolic acidosis and hypocitraturia should be treated with a combination of sodium citrate (or bicarbonate) and potassium citrate (or bicarbonate). Large amounts (1 to 2 mmol/kg daily in two or three divided doses) are often required to neutralize the acidosis.⁷

Hyperuricosuria

Calcium oxalate crystals often nucleate around other crystal types, such as uric acid. Hyperuricosuria contributes to nephrolithiasis in 10% to 15% of calcium stones. Patients with hyperuricosuric calcium oxalate nephrolithiasis have hyperuricosuria

with normal urinary calcium and oxalate but often a higher urinary pH (>5.5) than that of patients with pure uric acid stones. Therapy for hyperuricosuria consists of increased fluid intake and reduced dietary purine intake. If uric acid excretion remains elevated, allopurinol should be initiated at 100 to 300 mg daily.^{67,68}

Uric Acid Stones

Epidemiology

The prevalence of uric acid stones depends greatly on geographic location. In the United States, uric acid stones represent 5% to 10% of all stones formed, whereas in Mediterranean and Middle East countries, uric acid stones may be as high as 75%. The stones are radiolucent and therefore poorly visible on plain radiographs. They are detectable on ultrasound and CT and as filling defects on IVU (Fig. 57.14).

Etiology and Pathogenesis

Causes of hyperuricosuria include excessive dietary purine or protein intake, disorders associated with cellular breakdown (tumor lysis syndrome, myeloproliferative disorders, hemolytic anemia), gout, uricosuric medications, certain inborn errors of metabolism, and possibly excessive fructose intake.

Three major factors influence uric acid stone formation: low urine pH, low urine volume, and elevated urinary uric acid levels (Fig. 57.15). Uric acid is poorly soluble at pH below 5.5. Solubility increases with urine alkalinity, such that at urine pH 6.5, urine

Figure 57.14 Radiolucent urate calculi. Antegrade pyelogram showing multiple radiolucent urate stones (arrows) obstructing the lower ureter.

Uric Acid Stones
Low Urine pH (≤ 5.5)
High animal protein diet
Diarrhea
Insulin resistance (high body mass index, metabolic syndrome, type 2 diabetes)
Low Urine Volume
Inadequate fluid intake
Excessive extrarenal fluid losses
Diarrhea
Insensible losses (e.g., perspiration)
Hyperuricosuria
Excessive dietary purine intake
Hyperuricemia
Gout
Intracellular-to-extracellular uric acid shift
Myeloproliferative disorders
Tumor lysis syndrome
Inborn errors of metabolism
Lesch-Nyhan syndrome
Glucose-6-phosphatase deficiency
Medications (see Fig. 57.6)

Figure 57.15 Uric acid stones.

can contain more than six times the quantity of uric acid present at pH 5.3, without exceeding supersaturation. The rising incidence of obesity and insulin resistance in the United States has led to a parallel increase in uric acid lithiasis. The urinary acidosis is likely due to impaired ammoniogenesis, which results in excessive excretion of unbuffered acid and a very low urine pH.^{6,10,69-71}

Treatment

Treatment of uric acid stones involves increasing urine volume and pH as well as decreasing uric acid excretion. Alkaline urine can prevent uric acid stone formation and may also result in stone dissolution. To raise urine pH, potassium citrate is recommended. Whereas sodium bicarbonate alkalinizes the urine and enhances uric acid solubility, the added sodium increases sodium urate formation, which serves as a nidus for calcium oxalate precipitation. Potassium citrate (40 to 50 mmol/day in divided doses) is given, increasing the dose as necessary to achieve a urine pH of 6.5 to 7. Patients should monitor pH with urine dipsticks at various times of the day and adjust dosing accordingly. If urine pH remains low despite potassium citrate above 100 mmol daily or if that dose results in hyperkalemia, acetazolamide is added. This carbonic anhydrase inhibitor produces an alkaline urine similar to that seen in renal tubular acidosis. Patients should be cautioned not to exceed a urine pH of 7 because this may result in calcium phosphate precipitation.

A low-purine and low-animal protein diet is also useful in raising urinary pH and decreasing uric acid excretion (see Fig. 57.7). If uric acid excretion remains high despite dietary intervention, as in patients with disorders of cellular catabolism, allopurinol should be prescribed, 100 mg increasing to 300 mg daily as needed to keep urinary uric acid excretion below 750 mg/24 h

Factors Associated with Struvite Stone Formation
Urease-producing bacteria*
<i>Proteus</i>

(4.5 mmol/24 h). See Figure 57.7 for high-purine foods to be avoided.⁷²

Struvite Stones

Struvite stones are also referred to as infection stones or triple phosphate stones. The stones grow rapidly to a large size, can reduce renal function in the affected kidney, and are difficult to eradicate. Because of the significant morbidity in patients with struvite stones, they have also been termed stone cancer. Most staghorn calculi, large stones that penetrate more than one renal calyx, are composed of struvite. Their formation requires the presence of urease-producing bacteria in the urine (Fig. 57.16).⁷³

Etiology and Pathogenesis

Struvite stones form when urease production by urinary bacteria results in the formation of ammonium ions as well as alkaline urine. In this setting, phosphate is present in its trivalent form and combines with three cations, ammonium, magnesium, and calcium, the last as a component of carbonate apatite. Women are more prone to struvite nephrolithiasis than men are because of an increased propensity to UTI. Others predisposed to development of struvite stones through infections or urinary stasis include patients with indwelling urinary catheters, neurogenic bladders, genitourinary tract anomalies, and spinal cord lesions. An alkaline urine (pH 7), urease-producing bacteria in the urine, and large stones suggest the diagnosis of struvite nephrolithiasis.⁷³

A number of gram-negative and gram-positive bacteria have been implicated in urease production and consequent struvite formation; the most common are *Proteus* species (see Fig. 57.16). *Escherichia coli*, which is frequently present in urine cultures, is not a urease producer. If there is a strong suspicion of struvite stones but no organism is detected in the urine, a specific culture request for *Ureaplasma urealyticum* should be considered because it does not grow on routine culture media.

Treatment

Struvite stones require aggressive medical and surgical management. Antibiotic therapy is important to reduce further stone growth and for stone prevention. Bacteria will remain in the stone interstices, however, and stones will continue to grow unless chronic antibiotic suppression is maintained or the calculi are completely eradicated. Given the need for complete stone removal to effect a cure, early urologic intervention is advised. Stones

smaller than 2 cm may respond well to extracorporeal shock wave lithotripsy; however, larger stones will likely require percutaneous nephrolithotomy often in combination with extracorporeal shock wave lithotripsy (see Chapter 59). Any stone fragments retrieved should be cultured and culture-specific antibiotics continued. Once the urine is sterile, usually around 2 weeks after initiation of therapy, the dose is halved. Monthly urine cultures should be obtained, and if they remain sterile for 3 consecutive months, antibiotics may be discontinued, although surveillance urine cultures should continue monthly for a full year.⁷⁴

Adjunct medical therapies include urease inhibitors and chemolysis. The most commonly used urease inhibitor is aceto-hydroxamic acid. By inhibiting urease, these agents retard stone growth and prevent new stone formation. Unfortunately, they have numerous side effects that limit their use, although adverse effects resolve on discontinuation of the drug. In addition, they require adequate renal clearance to be effective and therefore are not useful in patients with renal impairment (estimated GFR <60 ml/min).^{73,75} Chemolysis refers to irrigation of the kidney through a nephrostomy tube or the ureter with a solution designed to dissolve the stones. The most common solution is 10% hemiacidrin, which contains carbonic acid, citric acid, D-gluconic acid, and magnesium at pH 3.9. Lavage chemolysis is controversial as it has previously been associated with a high mortality rate, but it is now considered safe with appropriate monitoring for UTI, assessment of obstruction to flow by intrapelvic pressure measurement, and monitoring of serum magnesium levels. Although it is not a treatment of choice for large stones, it may be useful when surgical techniques have been effective but have left residual stone fragments.

Cystine Stones

Cystinuria is an autosomal disorder in which there is a tubular defect in dibasic amino acid transport, resulting in increased cystine, ornithine, lysine, and arginine excretion (see Chapter 48). The pattern of inheritance may be autosomal recessive or autosomal dominant with incomplete penetrance. The stone disease is usually clinically manifested by the second and third decades of life. Because of the high sulfur content of the cystine molecule, the stones are apparent on plain radiographs (see Fig. 57.9A) and will often present as staghorn calculi or multiple bilateral stones.

Cystine is poorly soluble, only approximately 300 mg/l (1.25 mmol/l) at a neutral pH. Normal cystine excretion of approximately 30 to 50 mg (0.12 to 0.21 mmol) per day is readily soluble in the usual daily urine output of approximately 1 liter. However, homozygote cystinurics often excrete 250 to 1000 mg (1.04 to 4.20 mmol) of cystine per day; heterozygotes excrete an intermediate amount. Treatment must be directed at decreasing the urinary cystine concentration below the limits of solubility. Because the dietary precursor of cystine, methionine, is an essential amino acid, it is impractical to reduce intake. Increasing urine volume so that cystine remains below the limits of solubility sometimes requires 4 liters of urine per day. A low-sodium diet has been reported to reduce urine cystine excretion.⁷⁶ Increasing urine pH above 7.5 will increase cystine solubility, but this is difficult to achieve on a long-term basis. D-Penicillamine (starting dose, 250 mg daily; maximum dose, 2 g daily) and tiopronin will bind cystine and reduce urinary supersaturation; however, side effects may limit their use. The angiotensin-converting enzyme inhibitor captopril may be effective by forming a thiol-cysteine disulfide bond that is more soluble than cystine.⁷⁷

Stones Associated with Melamine Exposure

Since September 2008, more than 50,000 Chinese children younger than 3 years have been described with kidney stones associated with contaminated milk products. Powdered milk and infant formulas were noted to contain melamine, a nitrogenous substance synthesized from urea that increases the apparent protein content of the product.¹¹⁻¹³ Risk factors for nephrolithiasis after melamine exposure may include volume depletion, small body size, uricosuria, and low urine pH.

Whereas affected children often presented with dysuria and hematuria, many children who were subsequently screened were asymptomatic despite kidney stones identified by ultrasound.¹³ On urinalysis, some children exhibited fan-shaped crystals. The kidney stones formed were radiolucent and fragile. Many were composed of a combination of uric acid with melamine and were amenable to dissolution by hydration and alkalization. In animal studies of melamine exposure, the distal tubular crystal deposition may lead to tubulointerstitial inflammation and fibrosis. Whether a similar process may occur in humans is unknown.¹¹⁻¹³

NEPHROCALCINOSIS

Nephrocalcinosis refers to augmented calcium content within the kidney.^{16,78} This disorder may be symmetric or, in anatomic disorders such as medullary sponge kidney, involve only a single kidney.

Etiology and Pathogenesis

Medullary Nephrocalcinosis

Medullary nephrocalcinosis, in which the calcification tends to occur in the area of the renal pyramids, accounts for the majority of cases of nephrocalcinosis. It is typically associated with elevated urinary calcium, phosphate, and oxalate, or it can occur with alkaline urine (Fig. 57.17). Any disorder that can lead to hypercalcemia or hypercalciuria may be implicated. Instead of stone formation, smaller parenchymal calcifications are deposited in the medulla, which are usually bilateral and relatively symmetric (Fig. 57.18). Some metabolic disorders, particularly oxalosis due to primary hyperoxaluria, can result in both medullary and cortical nephrocalcinosis (Fig. 57.19).⁷⁸

In adults, the most common causes of medullary nephrocalcinosis are primary hyperparathyroidism, distal renal tubular acidosis, and medullary sponge kidney (see Chapter 45) as well as medications including acetazolamide, amphotericin, and triamterene (see Fig. 57.6).

Whereas a similar range of disorders can be seen in children, the most common associations are with furosemide therapy and the hereditary disorders associated with hypercalciuria.^{16,23} Furosemide, when it is used in premature neonates and older infants with congestive heart failure, can result in nephrocalcinosis with or without hypercalciuria. The lesions often resolve with discontinuation of therapy. A normal calcium to creatinine ratio at the time of diagnosis of nephrocalcinosis (approximately 0.40 [mg/mg] in premature infants) appears to be a good predictor of resolution.

Many uncommon hereditary disorders are associated with nephrocalcinosis. These include X-linked hypercalciuric nephrolithiasis, X-linked hypophosphatemic rickets, hypomagnesemia-hypercalciuria syndrome, and Bartter syndrome.

X-linked hypercalciuric nephrolithiasis is also termed Dent disease in the United Kingdom, low-molecular-weight protein-

uria with hypercalciuria and nephrocalcinosis in Japan, and X-linked recessive hypophosphatemic rickets in Italy.⁷⁹ A number of mutations affecting the *CLCN5* gene on the X chromosome have been identified that lead to inactivation of CLC-5 voltage-gated chloride channels. The result is a clinical syndrome typically affecting young boys and usually including hypercalciuria, nephrocalcinosis, nephrolithiasis, and hematuria as well as low-

Figure 57.19 Nephrocalcinosis. Dense cortical and medullary calcification in the shrunken kidneys of a patient with oxalosis and long-standing renal failure.

molecular-weight proteinuria, glycosuria, aminoaciduria, hypophosphatemia, renal failure, and rickets.^{79,80}

In X-linked hypophosphatemic rickets, the recommended treatment, with phosphate repletion and vitamin D, may itself result in hypercalcemia, hypercalciuria, and nephrocalcinosis.

Another cause of medullary nephrocalcinosis in children is primary hypomagnesemia-hypercalciuria syndrome.^{15,16,81} This rare autosomal recessive condition results from defective production of the cellular tight junction protein paracellin 1. This claudin family protein is necessary for adequate calcium and magnesium reabsorption in the thick ascending limb of the loop of Henle. Children typically present with symptoms of UTI (often with nephrolithiasis), polyuria, tetanic seizures (due to hypomagnesemia), and muscle cramps and weakness. Hypercalciuria, hypermagnesuria, and a urinary concentrating defect also occur. Patients often have renal impairment and may require renal replacement therapy by the third decade of life. Sensorineural hearing disorders and ocular impairment may accompany the renal manifestations in a subset of patients. These inherited tubular disorders are discussed further in Chapter 48.

Cortical Nephrocalcinosis

Cortical nephrocalcinosis is usually the result of dystrophic calcification, which follows parenchymal tissue destruction rather than the precipitation of excessive urinary constituents. It is secondary to infarction, neoplasm, and infection. It is typically asymmetric and is usually localized to the renal cortex (Fig. 57.20). Causes of cortical nephrocalcinosis include transplant rejection, cortical necrosis, tuberculosis, ethylene glycol toxicity, and chronic glomerulonephritis.

Clinical Manifestations

Patients who do not have nephrolithiasis associated with nephrocalcinosis are often asymptomatic. Ultrasound and CT scanning are sensitive diagnostic tests for both cortical and medullary nephrocalcinosis, demonstrating the parenchymal calcifications before they can be visualized on plain radiographs. The extent of calcification correlates poorly with renal function.

Figure 57.20 Cortical nephrocalcinosis. Non-contrast-enhanced CT scan showing cortical nephrocalcinosis (arrows) in the right kidney after cortical necrosis.

Treatment

Similar to treatment of nephrolithiasis, treatment of nephrocalcinosis relies on therapy for the underlying disease as well as measures to reduce hypercalcemia, hyperphosphatemia, and oxalosis, if possible.⁸² The goal of treatment is usually to prevent further deposits as therapy cannot eradicate existing calcium deposits.

Urinary Tract Obstruction

Kevin P.G. Harris, Jeremy Hughes

DEFINITIONS

Obstructive uropathy refers to the structural or functional changes in the urinary tract that impede normal urine flow. Obstructive nephropathy refers to the renal disease caused by impaired flow of urine or tubular fluid. Hydronephrosis refers to dilation of the urinary tract. Importantly, hydronephrosis is not synonymous with obstructive uropathy as it can occur without functional obstruction to the urinary tract and can be absent in established obstruction. Obstructive uropathy and nephropathy frequently coexist, and their management requires close collaboration between nephrologists and urologists. Some surgical aspects of obstruction to the urinary tract are discussed in Chapter 59.

Obstructive uropathy is classified according to the site, degree, and duration of the obstruction. Acute or chronic obstruction can occur anywhere in the urinary tract and includes intrarenal causes (casts, crystals) and extrarenal causes. Acute or chronic obstruction is further subdivided into upper urinary tract obstruction (usually unilateral obstruction occurring above the vesicoureteral junction) and lower urinary tract obstruction (usually bilateral obstruction located below the vesicoureteral junction). Complete obstruction of the urinary tract is termed high grade, whereas partial or incomplete obstruction is termed low grade.

Unilateral obstruction in a patient with two normal kidneys will not result in significant renal impairment because the contralateral kidney compensates. However, bilateral obstruction or the obstruction of a single functioning kidney will result in renal failure. In acute urinary tract obstruction, changes are mainly functional, whereas structural damage to the kidney results from more chronic obstruction. The acute functional changes may recover after the effective release of the obstruction, but structural changes may be permanent and lead to chronic renal impairment. Urinary tract obstruction remains a major cause of renal impairment worldwide.

ETIOLOGY AND PATHOGENESIS

The causes of obstructive uropathy affecting the upper and lower urinary tracts are summarized in [Figures 58.1 and 58.2](#).

Congenital Urinary Tract Obstruction

Congenital urinary tract obstruction occurs most frequently in males, most commonly as a result of either posterior urethral valves or pelviureteral junction obstruction. If obstruction occurs early during development, the kidney fails to develop and

becomes dysplastic. If the obstruction is bilateral, there is a high mortality rate as a result of severe renal failure. If the obstruction occurs later in gestation and is low grade or unilateral, hydronephrosis and nephron loss will still occur, but renal function may be sufficient to allow survival, and such patients may not present until later in childhood. Pelviureteral junction obstruction, if it is mild, may not present until adulthood and in some patients may be an incidental finding ([Fig. 58.3](#)). However, with increased use and improved sensitivity of antenatal scanning, congenital abnormalities of the urinary tract are now frequently identified early, allowing prompt postnatal (and in some cases antenatal) intervention to relieve the obstruction and hence to preserve renal function. Congenital causes of obstruction are discussed further in Chapter 50.

Acquired Urinary Tract Obstruction

Acquired urinary tract obstruction may affect either the upper or lower urinary tract and can result from either intrinsic or extrinsic causes. Intrinsic causes of obstruction may be intraluminal or intramural.

Intrinsic Obstruction

Intraluminal Obstruction Intraluminal obstruction may result from tubular intrarenal obstruction, such as the deposition of uric acid crystals in the tubular lumen after treatment of hematologic malignant neoplasms (tumor lysis syndrome). It may also occur with the precipitation of Bence Jones protein in myeloma and with the precipitation or crystal formation of a number of drugs, including sulfonamides, acyclovir, methotrexate, and indinavir (see Chapter 66).

Extrarenal intraluminal obstruction in young adults is most commonly caused by renal calculi (see Chapter 57). Calcium oxalate stones are the most common and typically cause intermittent acute unilateral urinary tract obstruction but rarely result in marked chronic renal impairment. Less common causes of urinary lithiasis, such as struvite stones, uric acid stones, and cystinuria, are often bilateral and hence more likely to cause long-term renal impairment. Renal calculi lodge more commonly in the calyx, pelviureteral junction, or vesicoureteral junction and at the level of the pelvic brim. Surgical management of stones is discussed in Chapter 59. Intraluminal obstruction can also result from a sloughed papilla after papillary necrosis or blood clots after macroscopic hematuria (clot colic). Papillary necrosis may occur in diabetes mellitus, sickle cell trait or disease, analgesic nephropathy, renal amyloidosis, and acute pyelonephritis. Clot colic can occur with bleeding from renal tumors or

Causes of Upper Urinary Tract Obstruction	
Intrinsic Causes	Extrinsic Causes
Intraluminal Intratubular deposition of crystals (uric acid, drugs) <i>Stones</i> Papillary tissue Blood clots Fungal ball	Reproductive system Cervix: <i>carcinoma</i> Uterus: <i>pregnancy, tumors, prolapse, endometriosis, pelvic inflammatory disease</i> Ovary: abscess, tumor, cysts Prostate: <i>carcinoma</i>
Intramural Functional: pelvic-ureteral or vesicoureteral junction dysfunction Anatomic: tumors (benign or malignant) Infections, granulomas, strictures	Vascular system Aneurysms: aorta, iliac vessels Aberrant arteries: pelviureteral junction Venous: ovarian veins, retrocaval ureter
	Gastrointestinal tract Crohn's disease Pancreatitis Appendicitis Diverticulitis Tumors
	Retroperitoneal space Lymph nodes Fibrosis: idiopathic, drugs, or inflammatory Tumors: primary or metastatic Hematomas Radiation therapy
	Surgical disruption or ureteral ligation

Figure 58.1 Causes of upper urinary tract obstruction. The most common causes are in italics.

Causes of Lower Urinary Tract Obstruction
Urethral anatomic causes Urethral strictures: trauma, <i>postinstrumentation</i> , infections such as gonococcal urethritis, nongonococcal urethritis, tuberculosis Posterior urethral valves Stones Blood clots Periurethral abscess Phimosis Paraphimosis Meatal stenosis
Urethral functional causes Anticholinergic drugs, antidepressants, levodopa
Prostate <i>Benign prostatic hypertrophy</i> <i>Prostatic carcinoma</i> Prostatic calculi Prostatic infection
Bladder anatomic causes <i>Bladder cancer</i> <i>Schistosomiasis (Schistosoma haematobium infection)</i> Bladder calculi Bladder trauma, pelvic fracture
Bladder functional causes <i>Neurogenic bladder</i> : spinal cord defects or trauma, diabetes, multiple sclerosis, Parkinson's disease, cerebrovascular accidents

Figure 58.2 Causes of lower urinary tract obstruction. The most common causes are in italics.

arteriovenous malformations, after renal trauma, and in patients with polycystic kidney disease.

Intramural Obstruction Intramural obstruction can result from either functional or anatomic changes. Functional disorders include vesicoureteral reflux, adynamic ureteral segments (usually at the junction of the ureter with the pelvis or bladder), and neurologic disorders. The last may result in a contracted (hypertonic) bladder or a flaccid (atonic) bladder, depending on whether the lesion affects upper or lower motor neurons, and lead to impaired bladder emptying with vesicoureteral reflux. Bladder dysfunction is very common in patients with multiple sclerosis and after spinal cord injury and is also seen in diabetes mellitus, in Parkinson's disease, and after cerebrovascular accidents. Some drugs (anticholinergics, levodopa) can alter neuromuscular activity of the bladder and result in functional obstruction, especially if there is preexisting bladder outflow obstruction (e.g., prostatic hypertrophy).

Anatomic causes of intramural obstruction of the upper urinary tract include transitional cell carcinoma of the renal pelvis and ureter and ureteral strictures secondary to radiotherapy or retroperitoneal surgery. Rarely, obstruction may result from ureteral valve malfunction, polyps, or strictures after therapy for tuberculosis. Intramural obstruction of the lower urinary tract can result from urethral strictures, which are usually secondary to chronic instrumentation or previous urethritis, or malignant and benign tumors of the bladder. Infection with *Schistosoma haematobium*, when the ova lodge in the distal ureter and bladder, is a common cause of obstructive uropathy worldwide; up to 50% of chronically infected patients develop ureteral strictures and fibrosis, with contraction of the bladder.

Extrinsic Obstruction

The most common cause of extrinsic compression in women is pressure from a gravid uterus on the pelvic rim; the right ureter

is more commonly affected. It is usually asymptomatic, and the changes resolve rapidly after delivery. Rarely, bilateral obstruction and acute kidney injury [AKI] may occur. Ureteral dilation may frequently be seen in pregnancy as a result of hormonal effects (especially progesterone) on smooth muscle, but this does not indicate functional obstruction (see Chapter 41, Fig. 41.1). Carcinoma of the cervix may also cause extrinsic obstruction because direct extension of the tumor to involve the urinary tract occurs in up to 30% of patients. Other pelvic pathologic processes that can cause ureteral compression include benign and malignant uterine and ovarian masses, abscesses, endometriosis, and pelvic inflammatory disease. Compression of the ureters outside the bladder may also occur with uterine prolapse. Although rare (<0.5%), inadvertent ureteric ligation may occur during surgical procedures, particularly those related to obstetrics and gynecology. Unilateral ligation may go undetected, but AKI will result from bilateral ligation.

In men, the most common cause of extrinsic obstruction of the lower urinary tract is benign prostatic hypertrophy. Carcinoma of the prostate can also result in obstruction either from direct tumor extension to the bladder outlet or ureters or from metastases to the ureter or lymph nodes.

Retroperitoneal disease may also result in extrinsic obstruction of the ureters, as can metastases or extension of tumors from the cervix, prostate, bladder, colon, ovary, and uterus. Primary tumors of the retroperitoneum, such as lymphomas and sarcomas, can commonly cause obstruction. Obstruction can also result from inflammatory conditions affecting the retroperitoneum, such as Crohn's disease and large bowel diverticulitis. In Crohn's disease, the obstruction is usually right sided as a result of ileocecal disease. Less common pathologic processes include retroperitoneal fibrosis, in which thick fibrous tissue extends out from the aorta to encase the ureters and draw them medially (Fig. 58.4). Retroperitoneal fibrosis may be idiopathic but can result from inflammatory aortic aneurysms, certain drugs (e.g.,

Figure 58.4 Retrograde pyelogram showing idiopathic retroperitoneal fibrosis. Dilation of the pelvicalyceal system is clearly demonstrated. The ureters, however, are not dilated, and the left ureter can be seen being pulled medially as a result of encasement in thick fibrous tissue.

β -blockers, bromocriptine, and methysergide), previous irradiation, trauma or surgery, and granulomatous disease (e.g., tuberculosis, sarcoidosis). Ureteral compression may also be a result of vascular abnormalities, including aneurysmal dilation of the aorta or iliac vessels, aberrant vessels, and anatomic variations in the location of the ureter (retrocaval ureter).

PATHOPHYSIOLOGY

Obstruction to the renal tract causes profound functional and structural changes of the kidney.¹ Initially, changes are predominantly functional and potentially reversible, but with time, chronic and irreversible structural changes occur. Our understanding of the consequences of urinary tract obstruction stem mainly from the study of animal models.² Although many studies have focused on the effects of complete ureteral obstruction in rodents, investigators have also examined models of chronic complete, partial, or reversible obstruction in adult and neonatal animals.³ Available experimental data show little species to species variation in the response to acute obstruction, suggesting that similar changes are likely to occur in humans. The complex effects of urinary tract obstruction on the kidney affect both glomerular hemodynamics and tubular function.⁴

Changes in Glomerular Function

Glomerular filtration rate (GFR) declines progressively after the onset of complete ureteral obstruction. Glomerular filtration is determined by the mean hydraulic pressure gradient between the glomerular capillary lumen and Bowman's space, the renal plasma flow, the ultrafiltration coefficient of the glomerular capillary wall, and the mean oncotic pressure difference across the glomerular wall. Obstruction can affect all of these, and the effects vary with the duration of the obstruction, the hydration state, and the presence or absence of a contralateral functioning kidney.

After complete ureteral obstruction, there is an initial rise in proximal tubular pressure. At the same time, afferent arteriolar dilation occurs as a result of the generation of vasodilatory prostaglandins (e.g., prostacyclin, prostaglandin E₂). Glomerular capillary hydraulic pressure increases, but this does not offset the rise in tubular pressure, and there is a net decrease in the hydraulic pressure gradient across glomerular capillaries, resulting in an 80% decline in GFR.

About 2 to 5 hours after obstruction, renal blood flow begins to decline, whereas intratubular pressure continues to increase. Within 5 hours, proximal tubular pressure begins to decline toward control values. From this time, the main determinant of the decrease in GFR is the fall in intraglomerular capillary pressure as a result of an increase in resistance of afferent arterioles. This results in a progressive fall in renal plasma flow, which reaches 30% to 50% of control values by 24 hours. Preferential constriction of the preglomerular blood vessels lowers both plasma flow and glomerular capillary pressure, resulting in a greater decrement in GFR than in plasma flow and a fall in filtration fraction. A falling filtration fraction also results from diversion of blood to nonfiltering areas of the kidney or a reduction in the ultrafiltration coefficient. The relative changes in ureteral pressure, renal plasma flow, and GFR are summarized in Figure 58.5.

The intrarenal vasoconstriction results from the generation of angiotensin II and thromboxane A₂, the release of vasopressin (antidiuretic hormone), and the decreased nitric oxide produc-

Figure 58.5 The effects of complete ureteral obstruction. The relative changes in ureteral pressure, renal plasma flow, and glomerular filtration rate are shown with data from experimental studies of unilateral ureteral obstruction in rats.

tion. Angiotensin II and thromboxane A_2 may also reduce the ultrafiltration coefficient.^{4,5} The central role of these two vasoconstrictors has been demonstrated by studies in rats, in which pretreatment with angiotensin-converting enzyme inhibitors and thromboxane synthase inhibitors virtually normalized renal function after the relief of short-term ureteral obstruction.⁶

Intrarenal angiotensin II generation occurs secondary to an increase in renin release either through reduced delivery of sodium and chloride to the distal nephron (macula densa mechanism) or through a reduction in transmural pressure at the baroreceptor as a consequence of the prostaglandin-dependent dilation of the afferent arteriole. Generation of thromboxane A_2 occurs in both glomeruli and infiltrating interstitial cells.

An interstitial leukocyte infiltrate, predominantly macrophages, develops in response to chemoattractants such as monocyte chemoattractant protein 1 and osteopontin expressed by tubular cells. This infiltrate plays a key role in the acute functional changes after ureteral obstruction⁷ and is implicated in the pathogenesis of the late structural changes that occur after obstruction as macrophage depletion limits interstitial fibrosis.⁸

The extent to which glomerular function recovers after the release of ureteral obstruction depends on the duration of the obstruction. Whole-kidney GFR may return to normal after short-term obstruction (days), whereas recovery may be incomplete after prolonged obstruction. Evidence from studies in rats now suggests that even with shorter periods of obstruction (72 hours), there may be a permanent loss of nephrons, and whole-kidney GFR returns to normal only at the expense of hyperfiltration (increase in single-nephron GFR) in the remaining functional nephrons.⁹

Changes in Tubular Function

Abnormalities in tubular function are common in urinary tract obstruction and are manifested as altered renal handling of electrolytes and changes in the regulation of water excretion.⁴ The degree and nature of the tubular defects after obstruction depend in part on whether the obstruction is bilateral or unilateral. These differences could result from the dissimilar hemodynamic

responses, different intrinsic changes within the nephron, differences in extrinsic factors (e.g., volume expansion and accumulation of natriuretic substances in bilateral obstruction) between the two states, or a combination of all three.

After ureteral obstruction, the ability to concentrate the urine is markedly impaired, with maximum values of 350 to 400 mOsm/kg reported in the rat. Causative factors include a loss of medullary tonicity, an overall decrease in GFR in deep nephrons, and a reduced expression of sodium transporters.¹⁰ Also, the collecting duct is unresponsive to vasopressin because of a reduction in the expression of renal aquaporins that results from both cyclooxygenase 2 activity¹¹ and angiotensin II.¹²

Rats exhibit reduced expression of multiple acid-base transporters after ureteral obstruction,¹³ and patients with urinary tract obstruction often exhibit urinary acidification defects. This may be detected only by exogenous acid loading, but hyperchloremic acidosis caused by impaired distal acid secretion, hyporeninemic hypoaldosteronism (type 4 renal tubular acidosis), and a combination of these findings have been described. This acidifying defect results from a marked increase in bicarbonate excretion or from a distal acidification defect, possibly as a result of abnormalities of the H^+ -ATPase activity of intercalated cells of the collecting duct after ureteral obstruction.

Obstruction alters renal potassium handling. In the presence of a normal functioning contralateral kidney, potassium excretion is reduced after relief of obstruction, either in proportion to or perhaps even greater than the fall in GFR (i.e., fractional excretion of potassium is unaltered or slightly reduced). There is a defect in the distal potassium secretory mechanism after unilateral obstruction that may be secondary to reduced responsiveness of that nephron segment to aldosterone. By contrast, after release of bilateral ureteral obstruction, there is a marked increase in both net and fractional potassium excretion. The major mechanism by which potassium losses occur in this setting is an increased delivery of sodium to the distal tubule, resulting in an accelerated sodium-potassium exchange.

Recovery of tubular function after release of obstruction is slow and may remain abnormal even after whole-kidney GFR has returned to normal. In rats, acidification and potassium handling abnormalities persist for at least 14 days and urinary concentrating ability is abnormal for up to 60 days after the release of 24 hours of unilateral ureteral obstruction. These observations are consistent with persistent alterations in distal tubular and collecting duct function or a loss in functioning juxtaglomerular nephrons after the release of the obstruction.

Histopathologic Changes

The morphologic alterations in renal architecture are similar irrespective of the cause of the obstruction. Initially, there is renal enlargement and edema with pelvicalyceal dilation (Fig. 58.6). Tubular dilation that predominantly affects the collecting duct and distal tubular segments develops microscopically, although cellular flattening and atrophy of proximal tubular cells can also occur. Glomerular structures are usually preserved initially, although Bowman's space may be dilated and contain Tamm-Horsfall protein. Ultimately, some periglomerular fibrosis may develop.

Inadequately treated obstruction to the urinary tract eventually causes irreversible structural changes to the renal tract. The renal pelvis becomes widely dilated, with the renal papillae either flattened or hollowed out. The cortex and medulla become grossly thinned, such that the kidney becomes a thin rim of renal tissue surrounding a large saccular pelvis (Fig. 58.7). Histologic

Figure 58.6 Autopsy specimen of a kidney showing the early effects of ureteral obstruction. The kidney is enlarged and edematous with pelvicalyceal dilation. There is good preservation of the renal parenchyma.

Figure 58.7 Chronic ureteral obstruction. Surgical specimen of a kidney showing gross dilation of the pelvicalyceal system and the reduction of the renal cortex to a thin fibrotic rim of tissue. There would have been no prospect for any significant functional recovery in this kidney after the relief of the obstruction.

examination demonstrates tubulointerstitial fibrosis and obliteration of nephrons. There is tubular proliferation and apoptosis, epithelial-mesenchymal transition, (myo)fibroblast accumulation, increased extracellular matrix deposition, and tubular atrophy. Ischemia as a result of the decreased renal blood flow contributes to the parenchymal damage after obstruction. In both genetic and interventional studies, an important pathologic role for angiotensin II and transforming growth factor β (TGF- β) has been established.^{14,15}

Infiltrating macrophages play a pivotal role in the chronic tissue injury and fibrosis that result from prolonged ureteral obstruction (Fig. 58.8).^{8,16} Interstitial macrophages release profibrogenic factors such as TGF- β and galectin-3, which promote progressive fibrosis. Local angiotensin II generation may also stimulate the production of TGF- β by tubular cells. Treatments shown to ameliorate chronic interstitial damage in experimental obstructive uropathy include angiotensin receptor blockers, pentoxifylline, simvastatin, and growth factors (such as bone morphogenetic protein 7, hepatocyte growth factor, and epidermal growth factor); beneficial effects include a reduction in tubulointerstitial inflammation and fibrosis, epithelial-mesenchymal

transdifferentiation, and tubular cell apoptosis.³ However, it is pertinent that differences have been noted in the response of adult and neonatal rodents to experimental therapeutic interventions, and it is unclear whether such differences might occur in humans.

EPIDEMIOLOGY

Obstructive uropathy is a common entity and can occur at all ages. The prevalence of hydronephrosis at autopsy is 3.5% to 3.8%, with about equal distribution between males and females,¹⁷ although this underestimates the true incidence as these figures exclude transient obstruction. The frequency and etiology of obstruction vary in both sexes with age. Antenatal ultrasound has significantly increased the detection rate of lower urinary tract obstruction in the fetus.¹⁸ In children younger than 10 years, obstruction is more common in boys; congenital urinary tract anomalies, such as urethral valves and pelviureteral junction obstruction, account for most cases. In North America, obstructive uropathy remains the most common cause of end-stage renal disease (ESRD) in pediatric patients registered for renal transplantation, accounting for 16% of cases. In addition, congenital obstructive uropathy accounts for 0.7% of all patients (median age, 31 years) maintained with renal replacement therapy, demonstrating the continued impact of this disease into adult life.¹⁹ In young adults (<20 years of age), the frequency of urinary tract obstruction is similar in males and females. Beyond 20 years of age, obstruction becomes more common in women, mainly as a result of pregnancy and gynecologic malignant neoplasms. The peak incidence of renal calculi occurs in the second and third decades of life with a threefold increased incidence in men. After the age of 60 years, obstructive uropathy occurs more frequently in men secondary to benign prostatic hypertrophy and prostatic carcinoma. About 80% of men older than 60 years have some symptoms of bladder outflow obstruction, and up to 10% have hydronephrosis. In Europe, acquired urinary tract obstruction accounts for 3% to 5% of the cases of ESRD in patients older than 65 years, with most resulting from prostatic disease.²⁰ In the United States, the number of patients receiving renal replacement therapy as a result of acquired obstruction continues to increase, accounting for 1.4% of prevalent patients, although the rise is not as rapid as with other causes of ESRD.¹⁹

CLINICAL MANIFESTATIONS

Obstruction of the urinary tract can present with a wide range of clinical symptoms, depending on the site, degree, and duration of obstruction.⁴ The clinical manifestations of upper and lower urinary tract obstruction differ. Symptoms can be caused by mechanical obstruction of the urinary tract (usually pain) or can result from the complex alterations in glomerular and tubular function that may occur in obstructive nephropathy. The latter commonly present as alterations in urine volume and as renal failure, which can be acute or chronic. For example, patients with complete obstruction present with anuria and AKI, whereas those with partial obstruction may present with polyuria and polydipsia as a result of acquired vasopressin resistance. Alternatively, there may be a fluctuating urine output, alternating from oliguria to polyuria. However, obstructive uropathy and hence obstructive nephropathy can occur without symptoms and with minimal clinical manifestations. Thus, obstruction of the urinary tract must be considered in the differential diagnosis of any patient with renal impairment.

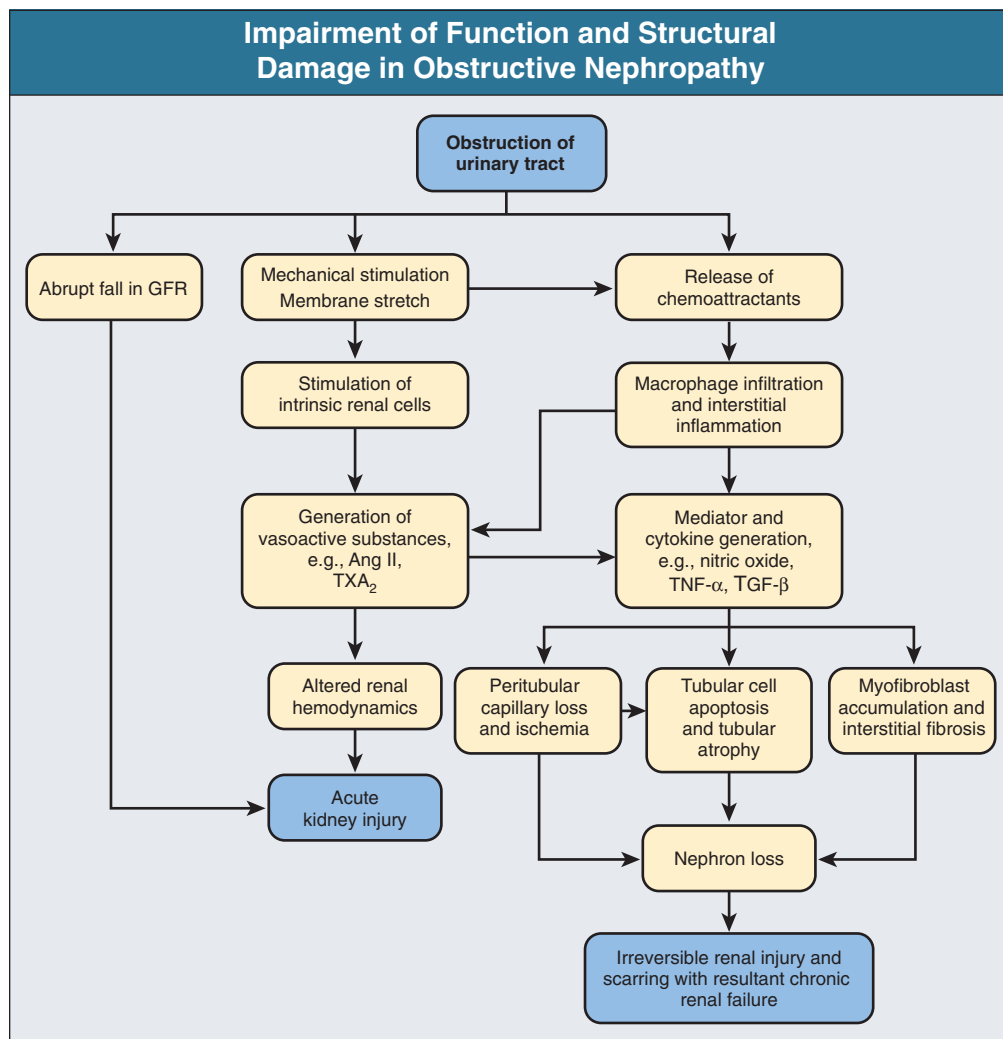

Figure 58.8 Events leading to acute impairment of renal function and chronic structural damage in obstructive nephropathy. Ang II, angiotensin II; GFR, glomerular filtration rate; TGF- β , transforming growth factor β ; TNF- α , tumor necrosis factor α ; TXA₂, thromboxane A₂.

Pain

Pain is a frequent complaint in patients with obstructive uropathy, particularly in those with ureteral calculi. The pain is believed to result from stretching of the collecting system or the renal capsule. Its severity correlates with the degree of distention and not with the degree of dilation of the urinary tract. On occasion, the location of the pain helps determine the site of obstruction. With upper ureteral or pelvic obstruction, flank pain and tenderness typically occur, whereas lower ureteral obstruction causes pain that radiates to the groin, the ipsilateral testicle, or the labia. Acute high-grade ureteral obstruction may be accompanied by a steady and severe crescendo flank pain radiating to the labia, the testicles, or the groin ("classic" renal colic). The acute attack may last less than half an hour or as long as a day. In contrast, pain radiating into the flank during micturition is said to be pathognomonic of vesicoureteral reflux. By comparison, patients with chronic, slowly progressive obstruction may have no pain or minimal pain during the course of their disease. In such patients, any pain that does occur is rarely colicky in nature. In pelviureteral junction obstruction, pain may occur only after fluid loading to promote a high urine flow rate.

Lower Urinary Tract Symptoms

Obstructive lesions of the bladder neck or bladder disease may cause a decrease in the force or caliber of the urine stream, intermittency, post-micturition dribbling, hesitancy, or nocturia. Urgency, frequency, and urinary incontinence can result from incomplete bladder emptying. Such symptoms commonly result from prostatic hypertrophy and are frequently referred to as prostatism, but they are not pathognomonic of this condition.

Urinary Tract Infections

Urinary stasis resulting from obstruction predisposes to urinary tract infections, and patients may develop cystitis with dysuria and frequency or pyelonephritis with loin pain and systemic symptoms. Infection occurs more often in patients with lower urinary tract obstruction than in those with upper urinary tract obstruction.

Urinary tract infection in men or young children of either sex, recurrent or persistent infections in women, infections with unusual organisms such as *Pseudomonas* species, and a single attack of acute pyelonephritis require further investigation to exclude obstruction. Also, the presence of obstruction makes

effective eradication of the infection difficult. Infections of the urinary tract with a urease-producing organism such as *Proteus mirabilis* predispose to stone formation. These organisms generate ammonia, which results in urine alkalization and favors the development of magnesium ammonium phosphate (struvite) stones. Struvite calculi can fill the entire renal pelvis to form a staghorn calculus that eventually leads to loss of the kidney if it is untreated. Thus, stone formation and papillary necrosis can also be a consequence of urinary tract obstruction as well as a cause of obstruction.

Hematuria

Calculi may cause trauma to the urinary tract uroepithelium and result in either macroscopic or microscopic hematuria. Any neoplastic lesion that obstructs the urinary tract, especially uroepithelial malignant neoplasms, may bleed, resulting in macroscopic hematuria. Urinary tract bleeding may also result in obstruction, giving rise to clot colic when it is in the ureter or clot retention when it is in the bladder.

Changes in Urine Output

Complete bilateral obstruction or unilateral obstruction of a single functioning kidney such as a renal transplant will result in anuria. However, when the lesion results in partial obstruction, urine output may be normal or increased (polyuria). A pattern of alternating oliguria and polyuria or the presence of anuria strongly suggests obstructive uropathy.

Abnormal Physical Findings

Physical examination findings can be completely normal. Some patients with upper urinary tract obstruction may have flank tenderness. Long-standing obstructive uropathy may result in an enlarged kidney that may be palpable. Hydronephrosis is a common cause of a palpable abdominal mass in children. Lower urinary tract obstruction causes a distended, palpable, and occasionally painful bladder. A rectal examination and, in women, a pelvic examination should be performed because they may reveal a local malignant neoplasm or prostatic enlargement.

Acute or chronic hydronephrosis, either unilateral or bilateral, may cause hypertension as a result of impaired sodium excretion with expansion of extracellular fluid volume or from the abnormal release of renin. On occasion, in patients with partial urinary tract obstruction, hypotension occurs as a result of polyuria and volume depletion.

Abnormal Laboratory Findings

Urinalysis may show hematuria, bacteriuria, pyuria, crystalluria, and low-grade proteinuria, depending on the cause of obstruction. However, urinalysis may be completely negative despite advanced obstructive nephropathy. In the acute phase of obstruction, urinary electrolyte values are similar to those seen in a “prerenal” state, with a low urinary sodium (<20 mmol/L), a low fractional excretion of sodium ($<1\%$), and a high urinary osmolality (>500 mOsm/kg). However, with more prolonged obstruction, there is a decreased ability to concentrate the urine and an inability to reabsorb sodium and other solutes. These changes are particularly marked after the release of chronic obstruction and give rise to the syndrome commonly referred to as postobstructive diuresis. Obstructive nephropathy may cause

secondary polycythemia as a result of increased erythropoietin production.

Increases in serum urea and creatinine are the most significant laboratory abnormalities in patients with obstructive uropathy. Electrolyte abnormalities may also occur, including a hyperchloremic hyperkalemic (type 4) metabolic acidosis or hyponatremia as a result of acquired nephrogenic diabetes insipidus. The development of obstruction in patients with underlying chronic kidney disease may accelerate the rate of progression. ESRD may occasionally be caused by chronic obstructive uropathy that had been asymptomatic.

Obstruction in Neonates or Infants

With the advent of routine antenatal scanning, the diagnosis of hydronephrosis and genitourinary abnormalities is now frequently made antenatally; however, unsuspected obstructive uropathy may present in the postnatal period with failure to thrive, voiding difficulties, fever, hematuria, or symptoms of renal failure. Oligohydramnios at the time of delivery should raise the suspicion of obstructive uropathy, as should the presence of congenital anomalies of the external genitalia. Nonurologic anomalies, such as ear deformities, a single umbilical artery, imperforate anus, or a rectourethral or rectovaginal fistula, should prompt investigation for urinary tract obstruction. Any infant with neurologic abnormalities may have a neurogenic bladder with associated obstructive uropathy.

DIAGNOSIS

Prompt diagnosis of urinary tract obstruction is essential to allow treatment to limit any long-term adverse consequences. Symptoms such as “renal colic” may suggest the diagnosis and prompt appropriate investigation. However, urinary tract obstruction should be actively considered in any patient with unexplained acute or chronic kidney impairment. The diagnostic approach has to be tailored to the clinical presentation (Fig. 58.9), but a careful history and thorough physical examination are mandatory in all patients.

Urinalysis may provide valuable diagnostic information. Hematuria suggests that the obstructing lesion is a calculus, sloughed papilla, or tumor. Bacteriuria suggests urinary stasis, especially in men or in pregnant women, but it may also be a complication of chronic obstruction. The presence of crystals in the urine sediment (cystine or uric acid) may be an indication of the type of stone causing the ureteral obstruction or the intrarenal obstruction resulting in AKI. Laboratory studies should include an assessment of renal function (serum creatinine and urea) and the measurement of serum electrolytes.

Imaging

Because the sites, causes, and consequences of obstruction to the renal tract are so variable, no single imaging investigation can diagnose renal tract obstruction with certainty. Thus, no single imaging investigation should be relied on to definitively exclude obstruction, especially if the clinical suspicion of obstruction is high. Therefore, the approach to the patient with suspected obstruction may require the complementary use of a number of different imaging techniques.

Ultrasound is the most widely used imaging modality, but the imaging approach to investigation of obstruction is changing. Computed tomography (CT) and magnetic resonance (MR)

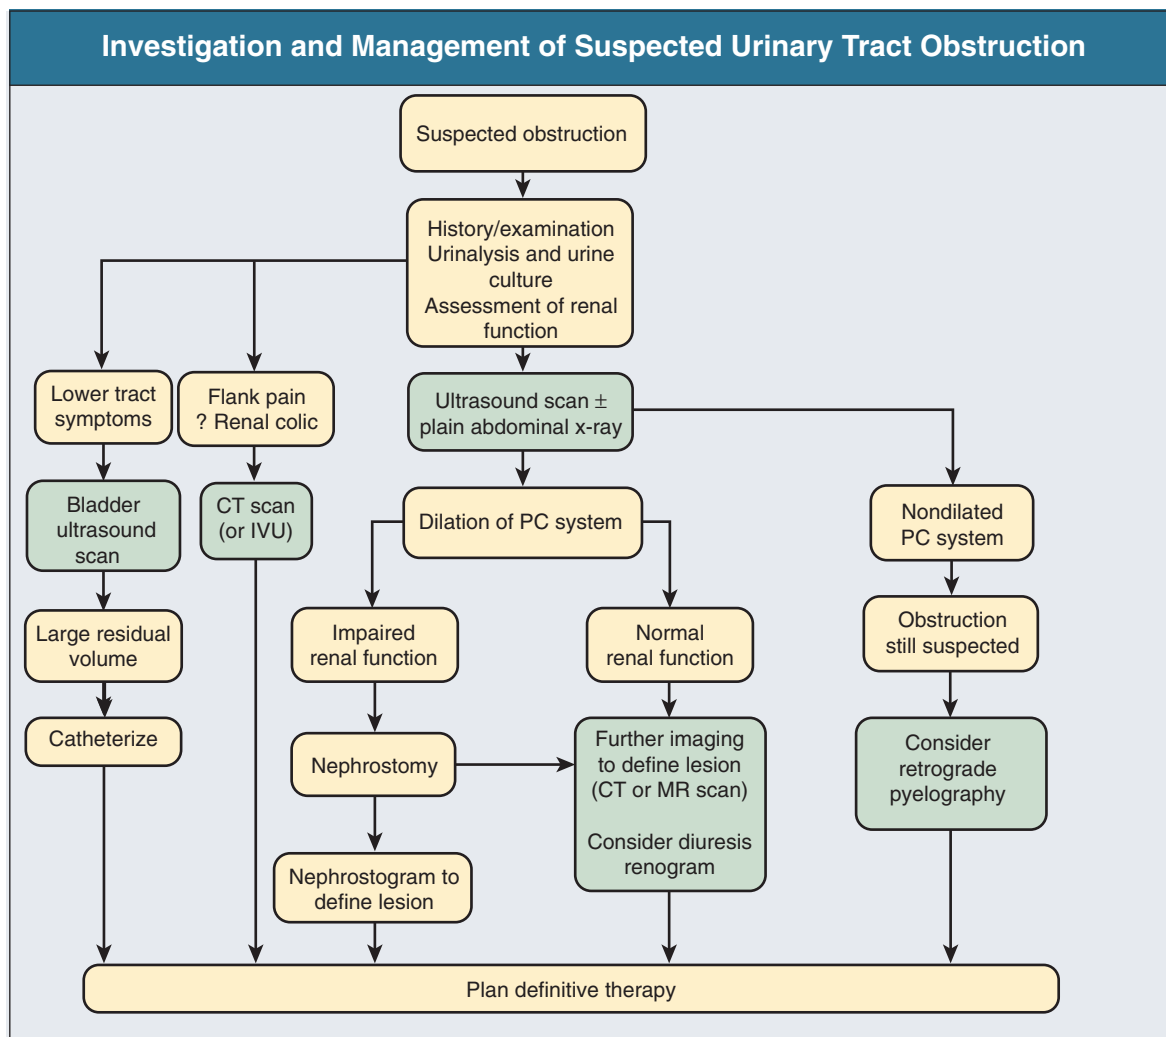

Figure 58.9 Investigation and management of suspected urinary tract obstruction. A full history and examination should be performed, together with urinalysis, urine microscopy and culture, and measurement of renal function and serum electrolytes. Ultrasound is a useful first-line investigation for any patient with suspected urinary tract obstruction. Helical (spiral) computed tomography (CT) is now the preferred imaging technique when renal calculi are suspected. Either CT or magnetic resonance (MR) urography can accurately diagnose both the site and the cause of obstruction in most cases. If there is renal impairment, insertion of a nephrostomy allows the effective relief of the obstruction and time for renal function to recover while definitive therapy is planned. IVU, intravenous urography; PC, pelvicalyceal.

urography are useful in accurately diagnosing both the site and the cause of obstruction, but the availability and expertise in the use of different imaging techniques vary from center to center, and older imaging techniques, such as intravenous urography (IVU), can still be used effectively to evaluate patients with obstructive uropathy. The role of imaging techniques is shown in Figure 58.9. Imaging is also discussed further in Chapter 5.

Ultrasound

Ultrasound can define renal size and demonstrate calyceal dilation²¹ (Fig. 58.10) but depends on the expertise of the operator. Although it is sensitive for detection of hydronephrosis, ultrasound will often not detect its cause. Pathologic change within the ureter is difficult to demonstrate, and tiny stones will not generate acoustic shadows. However, unilateral hydronephrosis suggests obstruction of the upper urinary tract by stones, blood clots, or tumors. Bilateral hydronephrosis is more likely to result from a pelvic problem obstructing both ureters or obstruction of the bladder outlet, in which case the bladder will also be enlarged.

Ultrasound is often combined with radiographic examination of the kidneys, ureters, and bladder (often known as KUB) to ensure that ureteral stones or small renal stones are not overlooked.

Ultrasound produces false-negative results in cases of nondilated obstructive uropathy.²¹ Immediately after acute obstruction (<24 hours), the relatively noncompliant collecting system may not have dilated, such that an ultrasound examination may be normal. Furthermore, if urine flow is low, as in severe dehydration or renal failure, there may be little dilation of the urinary tract. Dilation may also be absent in slowly progressive obstruction when the ureters are encased by fibrous tissue (as in retroperitoneal fibrosis) or by tumor. The acoustic shadow of a staghorn calculus can also mask dilation of the upper urinary tract. The sensitivity of ultrasound for diagnosis of obstruction can be improved by measuring the resistive index with color Doppler ultrasound. A resistive index above 0.7 reflects the increased vascular resistance present in obstruction and effectively discriminates between obstructed and nonobstructed kidneys.²¹ Such ultrasound techniques are particularly useful when it is especially important to minimize radiation exposure,

Figure 58.10 Renal ultrasound scan of a patient with obstruction of the urinary tract causing hydronephrosis. The kidney is hydronephrotic with dilation of the pelvicalyceal system; dilation of the upper ureter is also clearly seen (arrows).

for example, in pregnant women and children, and in the follow-up of patients requiring repeated imaging, such as after extracorporeal shock wave lithotripsy.

Even in experienced hands, ultrasound may have a significant false-positive rate, especially if minimal criteria are adopted to diagnose obstruction. In addition, the echogenicity produced by multiple renal cysts may be mistaken for hydronephrosis.

Ultrasound scanning can be used to assess bladder emptying and should be undertaken in patients with lower urinary tract symptoms. A large post-micturition residual volume suggests bladder outflow obstruction, which should prompt further urologic investigation and treatment.

The investigation of neonates with hydronephrosis diagnosed antenatally depends on the grade of hydronephrosis identified. Neonates with grade 1 or 2 hydronephrosis (no calyceal dilation) undergo ultrasound scanning; neonates with grade 3 to 5 hydronephrosis (indicating increasingly severe pelvicalyceal dilation) require both ultrasound scanning and voiding cystourethrography. This combination can distinguish megaureter resulting from obstruction or reflux and diagnose posterior urethral valves and ureteropelvic junction obstruction.

Plain Abdominal Radiography

A plain abdominal radiograph (or KUB) allows an assessment of kidney size and contour and frequently demonstrates renal calculi because about 90% of calculi are radiopaque.

Intravenous Urography

IVU was formerly the first-choice investigation for suspected upper urinary tract obstruction. In patients with normal renal function, it can usually define both the site and the cause of the obstruction. However, the excretion of contrast material may be poor or delayed in patients with low GFR because of a decreased filtered load of the contrast agent, which is potentially nephrotoxic. IVU is no longer a first-line investigation to diagnose urinary tract obstruction, especially in patients with impaired renal function.

Figure 58.11 CT scan of the abdomen showing a grossly hydronephrotic kidney on the left (arrows mark dilated renal pelvis). Dilated loops of small bowel are seen in the right hypochondrium. Sequential sections demonstrated that the ureter was dilated along its length and that there was a pelvic mass, which was responsible for both bowel and left ureteral obstruction. The mass was subsequently shown to be arising from a carcinoma of the colon.

Computed Tomography

Non-contrast-enhanced helical (spiral) CT scanning is used increasingly as the primary imaging modality for the evaluation of patients with acute flank pain.²² Stones are easily detected because of their high density, and CT can provide an accurate and rapid diagnosis of an obstructing ureteral calculus. In addition, it provides useful information about the site and nature of the obstructing lesion, especially when this is extrinsic to the urinary tract (Fig. 58.11; see also Chapter 59, Fig. 59.2). CT demonstrates retroperitoneal disease, such as para-aortic and paracaval lymphadenopathy; retroperitoneal fibrosis is evident as increased attenuation within the retroperitoneal fat, with encasement of one or both ureters. Hematomas, primary ureteral tumors, and polyps are also detectable. The diagnostic potential of CT is enhanced by the administration of contrast material, but this may limit its use in patients with renal impairment. In addition, it involves considerable exposure to ionizing radiation.

Magnetic Resonance Urography

MR urography (combined with KUB) can diagnose ureteral obstruction due to renal calculi with accuracy similar to that of spiral CT scanning but without exposure to contrast medium or ionizing radiation. The technique has less observer variability and is more accurate than CT in detecting indirect evidence of obstruction, such as perirenal fluid.²³ MR urography can rapidly and accurately depict the morphologic features of dilated urinary tracts and provide information about the degree and level of obstruction (Fig. 58.12).²⁴ MR urography is a particularly attractive imaging modality for the evaluation of hydronephrosis in children as it provides both anatomic and functional data and can indicate whether the hydronephrosis is compensated (symmetric changes of signal intensity of the nephrogram) or decompensated.²⁵ Signs of decompensation (acute on chronic obstruction) include edema of the renal parenchyma, a delayed and increasingly dense nephrogram, a delayed calyceal transit time, and a more than 4% difference in the calculated differential renal function. MR urography is likely to be increasingly used in the future.

Retrograde Pyelography

Retrograde pyelography (Fig. 58.13; see also Fig. 58.4) may be particularly useful to identify both the site and the cause of the

Figure 58.12 MR urography showing obstructive uropathy. T2-weighted MR image shows a proximal right-sided ureteral obstruction with an associated mild hydronephrosis. The obstruction was secondary to a ureteral calculus.

Figure 58.13 Ureteral obstruction by a tumor. A retrograde pyelogram shows that the tumor is within and obstructing the ureter (arrows). Above the tumor, there is dilation of the ureter; but below it, the ureter is of a normal caliber.

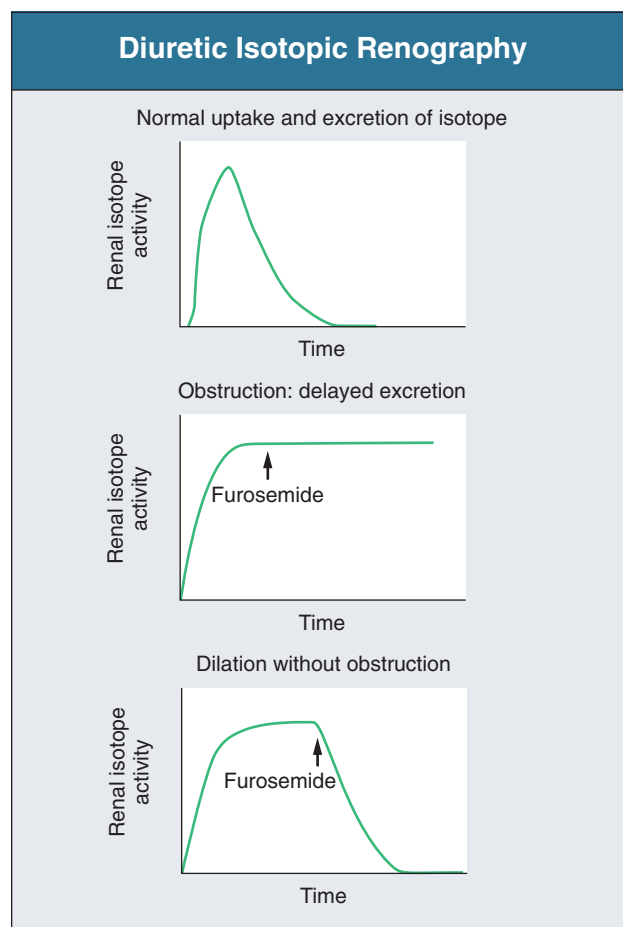

Figure 58.14 Diuretic isotopic renography. Idealized tracings for normal, obstructed, and dilated kidneys without obstruction of the upper urinary tract. In obstruction, there is delayed excretion of ^{99m}Tc -MAG3 despite administration of furosemide. When there is dilation of the upper urinary tract without obstruction, the isotope is retained but is rapidly excreted after the administration of furosemide.

obstruction. It is also helpful when nondilated urinary tract obstruction is suspected or when there is a history of allergic reactions to contrast material. Urinary tract infection that may become overwhelming if obstruction is present is a contraindication to retrograde pyelography.

Diuresis Renography

A diuresis renogram using technetium Tc 99m mercaptoacetyl-triglycine (^{99m}Tc -MAG3), combined with intravenous furosemide administered 20 to 30 minutes after injection of the isotope (diuretic isotopic renography), can be used to distinguish between simple dilation of the collecting system and true obstruction.²⁶ Normally, there is a rapid washout of the isotope from the kidney, and persistence of the isotope suggests a degree of obstruction (Fig. 58.14). Poor renal function significantly limits the usefulness of renography as the diuretic response to furosemide may be absent. Diuresis renography may also be used for follow up of patients who have undergone surgical procedures to relieve obstruction, such as a pyeloplasty.

Pressure-Flow Studies

A pressure-flow study (Whitaker test²⁷) involves puncture of the collecting system with a fine-gauge needle to perfuse fluid (at 10 ml/min) with concurrent measurement of the differential

pressure between the bladder and the collecting system; a pressure above 20 cm H₂O indicates obstruction. This test is now rarely required.

Other Evaluations

Lower urinary tract obstruction may be evaluated by cystoscopy, which allows a visual inspection of the entire urethra and the bladder. Urodynamic studies (see Chapter 50, Fig. 50.17) can assess bladder outlet obstruction, measure the residual urine volume after voiding, and detect functional bladder abnormalities. Although IVU with oblique films of the bladder and urethra during voiding (excretory cystography) and after voiding can also evaluate the site of lower urinary tract obstruction and the amount of residual urine, this has now largely been superseded by the use of ultrasound, CT, and MR urography.

DIFFERENTIAL DIAGNOSIS

Diagnostic uncertainty arises with nonobstructive dilation of the upper urinary tract that may be seen with vesicoureteral reflux, diuretic administration, diabetes insipidus, congenital megacalyces, chronic pyelonephritis, and postobstructive atrophy. Diuresis renography or retrograde pyelography may be required to exclude obstruction.

NATURAL HISTORY

Obstructive uropathy is potentially curable but will result in progressive irreversible loss of nephrons and renal scarring if it is left untreated (Fig. 58.15). ESRD will result if both kidneys are affected or if there is only a solitary kidney. Outcome data for obstructive uropathy are limited, but the exact prognosis will depend on the pathologic process responsible for the

Figure 58.15 Pathology of chronic ureteral obstruction. This is a section of the rim of renal tissue from the kidney shown in Figure 58.7. The renal capsule is at the top, the urinary space at the bottom. The cortex is considerably thinned, and only a few atrophic tubules remain (arrows) within an interstitium comprising dense fibrous tissue and a mononuclear cell infiltrate (blue-staining nuclei). No glomeruli can be seen. This demonstrates why there would be no prospect for any significant functional recovery in this kidney even after the relief of the obstruction.

obstruction, the duration of the obstruction, and the presence or absence of urosepsis. Relief of short-term obstruction (<1 to 2 weeks) usually results in an adequate return of renal function. With chronic progressive obstruction (>12 weeks), there is often irreversible and severe renal damage, and renal functional recovery may be limited even after relief of the obstruction. A single-center study identified 104 patients who presented with obstructive nephropathy.²⁸ The mean GFR at presentation and at 3, 12, and 36 months was 9 ml/min, 28 ml/min, 29 ml/min, and 30 ml/min (patients on dialysis excluded), demonstrating significant but nonprogressive renal impairment after relief of obstruction. It is likely that the prognosis for renal functional recovery is better the earlier the obstruction is diagnosed and relieved.

TREATMENT

General Considerations

Treatment is dictated by the location of the obstruction, the underlying cause, and the degree of any renal impairment. If renal impairment is present, the treatment of obstruction requires close collaboration between nephrologists and urologists to reduce the risks associated with the metabolic and electrolyte consequences of renal failure and to optimize the chances for long-term recovery of renal function. For example, complete bilateral ureteral obstruction presenting as AKI is a medical emergency and requires rapid intervention to salvage renal function. Prompt intervention to relieve the obstruction should result in a rapid improvement in renal function. Dialysis should rarely be required in patients with AKI secondary to obstruction except to make the patient fit for intervention, for example, by improving life-threatening hyperkalemia or severe fluid overload. The rapid relief of obstruction will limit permanent renal damage, but renal function may not recover immediately if acute tubular necrosis has resulted from obstruction or any accompanying sepsis.

Some surgical aspects of the management of obstructive uropathy are discussed in Chapter 59. The site of obstruction frequently determines the approach. If the obstruction is distal to the bladder, a urethral catheter or, if this cannot be passed, a suprapubic cystostomy will effectively decompress the kidneys. Placement of nephrostomy tubes or cystoscopy and passage of a retrograde ureteral catheter will relieve upper urinary tract obstruction. Percutaneous nephrostomy (PCN) is generally the appropriate emergency treatment of upper urinary tract obstruction, especially in the setting of AKI. PCN can be achieved with local anesthesia and should allow rapid recovery of renal function in most patients (>70%), avoiding the need for dialysis. After relief of the obstruction by PCN, the exact site and nature of the obstructing lesion can be determined by an antegrade study infusing radiographic contrast material into the nephrostomy tube (nephrostogram, Fig. 58.16), and time can be taken to plan definitive therapy. Major complications of nephrostomy insertion (abscess, infection, and hematoma) occur in less than 5% of patients. If both kidneys are obstructed, the nephrostomy should initially be placed in the kidney with the most preserved renal parenchyma, although bilateral nephrostomies may be required to maximize the potential for the recovery of renal function. If infection occurs above a ureteral obstruction (pyonephrosis), drainage of the kidney by PCN can play an important therapeutic role together with appropriate antibiotics.

A nephrostomy can be used to gauge the potential for functional recovery in patients with chronic obstruction. Failure of

Figure 58.16 Nephrostogram. A nephrostomy has been placed percutaneously into the dilated collecting system of the kidney under ultrasound control (A). After infusion of contrast material down the nephrostomy, the dilated pelvicalyceal system and upper ureter (B) and the lower ureter (C) are outlined. The ureter is dilated along its length but tapers abruptly at the vesicoureteral junction (arrow). In this case, the obstruction was caused by a radiolucent stone.

renal recovery after several weeks of nephrostomy drainage strongly suggests irreversible structural damage and thus no likely benefit from undertaking a more definitive surgical correction of the obstructing lesion. Long-term nephrostomy is increasingly used as a definitive therapy for patients who are unsuitable for major surgical intervention and those with incurable malignant disease (see Chapter 59 for further discussion).

Ureteral obstruction requiring intervention occurs in approximately 3% of renal transplant recipients.²⁹ It can be treated by nephrostomy and ureteric stenting, percutaneous incision or balloon dilation of the stricture, or open surgical repair (see Chapter 99).

Specific Therapies

Calculi are the most common cause of ureteral obstruction, and their treatment includes relief of pain, elimination of obstruction, and treatment of infection (see Chapter 59). Ureteral obstruction by papillary tissue, blood clots, or a fungus ball is treated by procedures similar to those used for calculi. When obstruction is caused by neoplastic, inflammatory, or neurologic disease, there is unlikely to be spontaneous remission of the obstruction, and some form of urinary diversion, such as an ileal conduit, should be considered. Some obstructing neoplastic lesions, such as lymphadenopathy from lymphoma, may respond to chemotherapy. Management of malignant urinary tract obstruction is discussed further in Chapter 59.

In idiopathic retroperitoneal fibrosis, ureterolysis (in which the ureters are surgically freed from their fibrous encasement) may be beneficial, especially in combination with corticosteroid therapy to prevent recurrence. A retrospective study demonstrated the effectiveness of ureteric stent insertion and corticosteroids in idiopathic retroperitoneal fibrosis.³⁰

Functionally significant pelviureteral junction obstruction should be corrected surgically by either an open (Anderson-Hynes) pyeloplasty or a laparoscopic approach. The laparoscopic approach results in significantly less morbidity and has good long-term outcomes that are identical to those of the open procedure. Balloon dilation of the abnormal segment of ureter is also possible, but the recurrence rate is high.

Benign prostatic hypertrophy is the most common cause of lower urinary tract obstruction in men and may be mild and nonprogressive. A patient with minimal symptoms, no infection, and a normal upper urinary tract can continue with assessment until he and his physician agree that further treatment is desirable. Medical therapy with either α -adrenergic blockers (e.g., tamsulosin) or 5 α -reductase inhibitors (e.g., finasteride) may be used in patients with moderate symptoms.³¹ α -Blockers relax the smooth muscle of the bladder neck and prostate and decrease urethral pressure and outflow obstruction. 5 α -Reductase inhibitors inhibit the conversion of testosterone to the active metabolite dihydrotestosterone and reduce prostatic hypertrophy. Combination therapy with these agents may be synergistic. Surgical intervention with transurethral resection of the prostate is generally required for failed medical treatment, debilitating symptoms, urinary retention, recurrent infection, or evidence of renal parenchymal damage. Holmium laser enucleation of the prostate is a less invasive alternative to transurethral resection of the prostate with good short-term and long-term outcomes.³²

Urethral strictures in men can be treated by dilation or direct-internal urethrotomy. The incidence of bladder neck and urethral obstruction in women is low and treatment rarely required. Suprapubic cystostomy may be necessary for bladder drainage in patients unable to void after injury to the urethra or in those who have an impassable urethral stricture.

When obstruction results from neuropathic bladder function, urodynamic studies are essential to determine therapy. The goals

of therapy are to establish the bladder as a urine storage organ without causing renal parenchymal injury and to provide a mechanism for bladder emptying that is acceptable to the patient. Patients may have either a flaccid atonic or an unstable hypertonic bladder. Ureteral reflux and parenchymal damage may develop in both cases, although it is more common in patients with a hypertonic bladder. Asking the patient to void at regular intervals may achieve satisfactory emptying of the bladder. Patients with an atonic bladder and significant residual urine retention associated with recurrent urosepsis need to undertake clean intermittent self-catheterization. The aim should be to catheterize four or five times per day to ensure that the amount of urine drained from the bladder on each occasion is less than 400 ml. External sphincterotomy has also been used in men with an atonic bladder and may relieve outlet obstruction and promote bladder emptying, but it may cause urinary incontinence and the need to wear an external collection device. In patients with a hypertonic bladder, improvement in the storage function of the bladder may be obtained with anticholinergic agents. On occasion, chronic clean intermittent self-catheterization is necessary.

Whenever possible, chronic indwelling catheters should be avoided in patients with a neurogenic bladder because they may lead to the formation of bladder stones, urosepsis, and urethral erosion, and they predispose to squamous cell carcinoma of the bladder. Patients who have chronic indwelling catheters for more than 5 years should have annual cystoscopic examinations. If deterioration in renal function occurs despite conservative measures or there is intractable incontinence or a small contracted bladder, an upper urinary tract diversion procedure such as an ileal conduit may be required.

Management of Postobstructive Diuresis

Marked polyuria (postobstructive diuresis) is frequently seen after the release of bilateral obstruction or obstruction of a single functioning kidney. Release of unilateral obstruction rarely results in a postobstructive diuresis³³ despite the presence of tubular dysfunction and a concentrating defect. This is due to intrinsic differences in the tubular response to unilateral and bilateral obstruction and, more important, the salt and water retention and renal impairment that occurred in bilateral obstruction (not evident in unilateral obstruction because of the contralateral normal kidney). The resultant increase in natriuretic factors (including atrial natriuretic peptide) and substances able to promote an osmotic diuresis, such as urea,³⁴ promote an appropriate postobstructive diuresis to excrete water and electrolytes that were retained during the period of obstruction. However, the postobstructive diuresis may also be inappropriate as a result of tubular dysfunction, and if it is not managed correctly, this may cause severe volume depletion and electrolyte imbalance with continued renal dysfunction. Intravenous and oral fluid replacement is usually required, with careful and regular clinical assessment of fluid balance and serum electrolytes to tailor the fluid replacement regimen appropriately. Once the patient is deemed euvoletic, urine losses plus an allowance for insensible losses should be replaced. Urine volume should be measured regularly (hourly) to facilitate fluid administration, and serum electrolytes should be measured at least daily and as frequently as every 6 hours when there is a massive diuresis. Daily weighing of the patient is also helpful. Replacement fluid regimens should include sodium chloride, a source of bicarbonate, and potassium. Calcium, phosphate, and magnesium replacement may also be necessary.

If fluid administration is overzealous, the kidney will not recover its concentrating ability, and a continued "driven" diuresis will result. It may then be necessary to decrease fluid replacement to levels below those of the urine output and to observe the patient carefully for signs of volume depletion.

Future Prospects

Understanding of the pathophysiologic changes that follow ureteral obstruction has allowed the development of rational interventional therapies to hasten the recovery of renal function and to limit permanent renal damage. Although the best treatment option in humans remains the prompt and effective relief of the obstruction, the development and implementation of improved imaging modalities that provide more sophisticated anatomic and functional information (including intrarenal oxygen content³⁵) will undoubtedly refine management and increase the data available for making key clinical decisions, such as whether and when surgical intervention is required.

Urologic Issues for the Nephrologist

Evangelos G. Gkougkousis, Sunjay Jain, J. Kilian Mellon

Close interaction between nephrologists and urologists is crucial to the optimal management of a number of common clinical problems. A proper understanding of urologic strategies helps the nephrologist ensure that patients presenting with these problems are given clear information and are optimally managed. Areas in which such coordinated work is most important are discussed in this chapter. They include the management of stone disease, the surgical approach to urinary tract obstruction, the investigation of hematuria, and the management of urinary tract malignant neoplasms.

SURGICAL MANAGEMENT OF STONE DISEASE

The management of urinary tract stones has been irrevocably changed by the introduction of extracorporeal shock wave lithotripsy (ESWL), percutaneous nephrolithotomy (PCNL), and ureteroscopy. Because of the effectiveness of ESWL, many endoscopic procedures for stones are now more complex than previously. Open stone surgical techniques are a second- or third-line treatment in most cases. [Figure 59.1](#) indicates the changing use of different modalities of stone treatment since the introduction of the newer techniques.¹

Advances in Imaging for Urinary Tract Stones

In recent years, unenhanced computed tomography (CT) scanning of the abdomen and pelvis has replaced intravenous urography (IVU) as the standard imaging modality for stone diagnosis ([Fig. 59.2](#)). CT offers increased sensitivity compared with IVU (99% versus 70%) without the need for the intravenous administration of contrast material. An additional advantage is the ability of CT to demonstrate radiolucent stones (mainly uric acid and xanthine stones) and to detect concomitant lesions leading to alternative diagnoses. CT does require an increased radiation dose, but this is lessening with modern machines. Comparative doses are 0.42 mSv for plain radiography of the kidneys, ureters, and bladder (KUB); 2.5 mSv for IVU; and 4 mSv for non-contrast-enhanced CT.

Treatment of Urinary Tract Stones

Spontaneous stone passage can be expected in up to 80% of patients with a stone size smaller than 4 mm. Conversely, for stones with a diameter of more than 7 mm, the chance of spontaneous stone passage is very low. The location is also important; up to 70% of distal ureteral stones pass spontaneously, in contrast to only 45% of midureteral and 25% of proximal ureteral

stones. Intervention is strongly recommended when there is persistent pain (>72 hours) despite adequate analgesia, persistent obstruction with risk of impaired renal function (e.g., with pre-existing renal impairment or in a single kidney), bilateral obstruction, or associated urinary tract sepsis.

Another conservative treatment option is chemolysis, as several stone types are in principle amenable to dissolution by oral medications or by direct instillation of chemical solutions. However, in most cases, this form of treatment is either impractical or clinically ineffective. The major exception is uric acid stones, which can readily be dissolved by alkalization of the urine, usually with oral potassium citrate.

Acute Surgical Intervention

The main goal of acute surgical intervention is to relieve obstruction. If the patient is considered well enough for general anesthesia, ureteroscopic stone destruction can be attempted in most cases. Alternatively, a double-J stent (a ureteral stent with two coiled ends) can be inserted, which will relieve obstruction until definite treatment is performed ([Fig. 59.3](#)). However, in the setting of uncontrolled urinary tract infection, percutaneous nephrostomy (PCN) is the preferred option because it can be done under local anesthesia and is less likely than endoscopic surgery to cause septicemia ([Fig. 59.4](#)). Rarely, an open procedure to remove a stone or a grossly infected kidney may be necessary.

Elective Surgical Intervention

Extracorporeal Shock Wave Lithotripsy

During ESWL, acoustic shock wave energy is delivered to a stone under fluoroscopic or ultrasound guidance. Treatment sessions typically last about 30 minutes, during which 1500 to 2500 shock waves are delivered. Sessions are performed on an outpatient basis under analgesia or intravenous sedation and can be repeated at intervals of 10 to 14 days. Stones up to 20 mm in size can be treated effectively, and stone-free rates of 60% to 98% have been reported. However, ESWL is operator dependent, and outcome is influenced by the size, composition, and location of the stone and the type of lithotripter used. Cystine and calcium oxalate monohydrate stones are especially resistant. Targeting of the stone may be impossible in the presence of obesity and skeletal deformities, and ESWL is contraindicated in patients with aortic or renal artery aneurysm, uncontrolled urinary tract infection, coagulation disorders and in pregnant women.

Changing Use of Techniques for Stone Removal			
	1984	1990	1999
Location (%)			
Calyceal stones	35	43	46

Staghorn stones	8	3	1
Ureteral stones	15	34	40
Treatment modality (%)			
ESWL	60	79	78
PCNL	20	5	2
Ureteroscopy	11	15	20
Open surgery	9	1	0.1

Figure 59.1 Changing use of techniques for stone removal. The changes in the application of surgical techniques for stone removal since the introduction of extracorporeal shock wave lithotripsy (ESWL) and percutaneous nephrolithotomy (PCNL). (Data from reference 1.)

Figure 59.2 CT scan demonstrating a ureteral calculus. Non-contrast-enhanced CT scan showing a calculus (arrow) at the right vesicoureteral junction.

A double-J ureteral stent is sometimes placed endoscopically before ESWL treatment to prevent stone fragments from obstructing the distal ureter (Steinstrasse, literally “stone street”; Fig. 59.5). Other acute complications of ESWL include hemorrhage or hematoma, infection, and injury to adjacent organs. The risk for the later development of hypertension or renal impairment after ESWL remains controversial.

ESWL is the first-line treatment for more than 75% of stone patients. Figure 59.6 shows circumstances in which ESWL is less effective and PCNL becomes the preferred surgical approach or a combination of the two modalities is used. For lower pole stones in particular, ESWL may not provide optimal clearance because of problems with the drainage of residual fragments. A randomized controlled trial has shown that for lower pole stones larger than 10 mm, PCNL has much better clearance rates than ESWL (92% versus 23%).²

Percutaneous Nephrolithotomy

During PCNL, a track is created between the skin and the collecting system of the kidney and used as a working channel to remove stones. Preoperatively, IVU or CT, sometimes with three-dimensional reconstruction, is used to accurately localize calculi and neighboring organs (e.g., spleen, liver, large bowel, pleura, or lungs) and to plan access. The most frequently used access site is the dorsal calyx of the lower pole, and stone fragmentation is undertaken by ultrasound, pneumatic, or laser

Figure 59.3 Ureteral stenting. Plain radiograph showing a double-J ureteral stent in the left ureter. Note that the curled ends of the stent remain in the pelvis and the bladder despite ureteral peristalsis.

Figure 59.4 Nephrostogram in ureteral obstruction due to a stone. Contrast material is injected through a percutaneous nephrostomy tube placed in the lower pole calyx (arrow). The contrast material outlines a single large calculus (arrowheads) producing complete obstruction at the pelviureteral junction.

devices. The PCNL technique is modified for special circumstances, usually by altering the site of puncture (e.g., directly into a calyceal diverticulum) or, if there are ureteral stones, by using a higher placed puncture to permit antegrade ureteroscopy. The percutaneous puncture may be facilitated by the preliminary placement of a retrograde ureteral catheter to dilate and to opacify the collecting system, which is then punctured under fluoroscopy. After completion of PCNL, a self-retaining balloon nephrostomy tube is used to tamponade the track and to provide

Figure 59.5 Extracorporeal shock wave lithotripsy complicated by Steinstrasse. **A**, Preoperative plain radiograph showing stones in the left renal pelvis. **B**, After ESWL, note the disappearance of the pelvic stone, the string of stone fragments throughout the length of the ureter, and the double-J ureteral stent placed to facilitate their passage.

further access if needed. Hemorrhage can complicate PCNL (from renal or, rarely, intercostal arteries) and can usually be treated conservatively or by selective angioembolization. Other complications include sepsis; fluid overload (“transurethral resection syndrome”); injury to spleen, pleura, or colon; and extravasation. PCNL usually results in minimal parenchymal injury, averaging only 0.15% of the total renal cortex.³

Indications for PCNL are shown in Figure 59.6. These continue to evolve and are being challenged by developments in ureteroscopic techniques, which are allowing more upper ureteral and renal pelvis stones to be dealt with by a retrograde approach.

Open Stone Surgery

Although it is performed rarely, open surgery still has a place in the treatment of stone disease. It is reported that approximately 2% of stone cases are treated with open surgery, mainly when anatomic factors preclude the use of minimally invasive methods or when these techniques have failed. Other indications include complex stone burden and the presence of intrarenal anatomic abnormalities (e.g., pelviureteral junction obstruction). During surgery, the renal pelvis as well as the parenchyma can be opened along avascular planes, and clamping of the renal vessels and hypothermia of the kidney may be needed. In selected cases, a laparoscopic approach, can be employed for the treatment of stone disease.

Ureteroscopy

Recent advances in the design of endoscopes for ureteronephroscopy have rendered the entire urinary tract accessible to endoscopic examination and manipulation. Ureteroscopes may be semirigid or flexible, the latter allowing access to the renal pelvis and calyces. Stone fragmentation is achieved ideally by laser but also by ultrasound or pneumatic devices. Laser is equally effective for all types of stones and has additional advantages of a flexible fiber (allowing intrarenal stone fragmentation), low

Indications for Percutaneous Nephrolithotomy		
Stone Size	Stone >3 cm or Staghorn	Treatment
Composition*	Struvite stones	Complete removal necessary to eliminate infection and minimize stone recurrence
	Calcium oxalate monohydrate stones	Difficult to pulverize by ESWL
	Cystine stones	Difficult to pulverize by ESWL
Stone position	Lower pole stones	Fragments less easily evacuated from dependent lower pole calyces, especially if collecting system dilated
Anatomic abnormalities	PUJ obstruction Calyceal diverticula	Prevent passage of fragments after ESWL
Patient characteristics	Morbid obesity Ureteral obstruction	Stone cannot be placed in focal point of ESWL machine

Figure 59.6 Indications for percutaneous nephrolithotomy. ESWL is the first choice for stone intervention, except in those circumstances that may favor PCNL. *Stone composition can be defined with certainty only by direct stone analysis, but advances in imaging may ultimately provide a means to accurately assess stone composition *in situ* before treatment, thus allowing the urologist to select the treatment most likely to be successful. PUJ, pelviureteral junction.

tissue penetration, and minimal stone displacement during use. Success rates for laser fragmentation of ureteral stones are high, in the region of 80%. Graspers and baskets can be used to manipulate stones or to remove fragments. However, because of the risk of ureteral avulsion, the use of baskets to remove intact stones is no longer recommended. Other complications of ureteroscopic techniques include perforation, extravasation, mucosal damage, hematuria, infection, and stricture.

Management of Staghorn Calculus

A staghorn calculus should usually be managed by intervention because reports of conservative therapy show a high rate of eventual nephrectomy (up to 50%) and an increase in associated morbidity (mainly renal failure) and mortality (up to 28%). Surgical options are ESWL monotherapy, complete endoscopic stone removal, and a combined approach using PCNL for debulking followed by ESWL. The advantage of the combined approach is the reduced need for additional renal access and secondary endourologic procedures. The choice of treatment depends on many factors, including the age and renal function of the patient. ESWL will not usually render the patient entirely stone free (the ideal goal of treatment), especially in the treatment of large staghorn stones; nevertheless, it can still be considered successful when less than 40% of a staghorn calculus persisting as fragments is achieved. Rarely, open surgical removal of the stone may be indicated.

Stones in Transplanted Kidneys

The management of stone disease in a transplanted kidney is challenging because of the solitary kidney, the anatomic location within the pelvis, and the difficulty with retrograde access to the ureter and kidney. Early active intervention is indicated; prophylactic stenting, ureteroscopy, and PCNL are preferred to ESWL because stone targeting may not be possible. Open surgery may be needed in selected cases.

MANAGEMENT OF URINARY TRACT OBSTRUCTION

The causes of upper tract obstruction are listed in Chapter 58, Figure 58.1, and a summary of the management of obstruction is given in Chapter 58, including Figure 58.9. Upper tract obstruction due to malignant disease can be a result of direct tumor invasion or external compression by metastatic lymph node involvement or, rarely, true metastasis to the ureter. Some 70% of tumors causing ureteral obstruction are genitourinary (cervical, bladder, prostate) in origin; breast and gastrointestinal carcinomas and lymphoma constitute the majority of the remainder.⁴ The presentation of a patient with obstruction may vary significantly, and hydronephrosis may develop progressively and insidiously and remain unrecognized until the patient presents with anuria and uremia. Upper tract obstruction due to malignant disease rarely presents with classic acute ureteral colic, which is typically seen with a benign cause such as a stone. Bladder outflow obstruction may be acute and dramatic; or chronic, with few or no symptoms. To understand the immediate needs and longer term prognosis of these patients, the acute as well as the definitive management of the most common urologic diseases associated with obstruction and renal impairment is outlined.

Acute Management of Urinary Tract Obstruction

Relief of obstruction is crucial to reverse renal impairment and to preserve remaining renal function. In cases of bladder outflow obstruction, a urethral or suprapubic catheter is indicated; whereas in upper tract obstruction, a double-J ureteral stent is preferable, when possible. The most straightforward approach is endoscopic retrograde placement under fluoroscopy, with PCN reserved for cases in which the procedure fails. Bilateral stents should be placed if it is technically possible. However, tumor infiltration can distort trigonal anatomy, making identification of ureteral orifices for double-J stent insertion impossible at the time of cystoscopy. Furthermore, it has been suggested that stents fail to relieve obstruction in 40% to 50% of cases of external ureteral compression. Thus, these patients need to be closely monitored to ensure resolution of the obstruction. A new type of metallic, self-expanding stent, used alone or in conjunction with double-J stents, has good results in maintaining ureteral patency and avoiding PCN in malignant ureteral obstruction.

A stable patient with obstruction but without major signs of sepsis is a candidate for retrograde stent placement under general anesthesia. However, in a septic patient, endoscopic manipulation can lead to rapid deterioration. Furthermore, such patients may not be fit for general anesthesia, in which case the preferred initial approach is PCN, which can then be followed after an interval with antegrade ureteral stenting. The success rate of this combined approach is high (>90%).⁵ In patients with bilateral ureteral obstruction, it is not always necessary to insert bilateral PCN tubes. Significant palliation and return to nearly normal renal function can be accomplished by drainage of a single kidney, preferably the unit with the better preserved parenchyma as determined by CT scan or ultrasound. Once they are placed, PCN tubes or double-J stents need to be replaced every 4 to 6 months. If they are left longer, they become increasingly brittle and encrusted and are liable to fracture or break when they are manipulated. Complications of ureteral stents include migration,

Figure 59.7 Extra-anatomic stenting for malignant ureteral obstruction. Plain radiograph showing placement of an extra-anatomic stent for malignant obstruction of the right ureter. The upper end of the double-J stent has been placed in the right renal pelvis (*arrow*). The stent then runs through a subcutaneous tunnel before the lower end enters the bladder (*arrowhead*).

obstruction with proteinaceous material, infection, fragmentation, and rarely erosion through the urinary tract.⁶ As many as 70% of patients with stents report lower urinary tract symptoms, mainly urgency, frequency, and nocturia as well as pain along the urinary tract.

Morbidity after stenting or PCN is similar.⁷ The main problem with indwelling stents is the increased risk of recurrent obstruction (11% for stents versus 1% for PCN). PCN may have an increased infection rate, and there may be psychological issues relating to the need for an external drainage bag.

Extra-anatomic stents are an alternative for patients in whom conventional stent insertion has failed or for whom permanent nephrostomy drainage is unacceptable. An extra-anatomic stent is placed by an initial percutaneous puncture and insertion of the upper end of a long (50-cm) double-J stent into the kidney. A subcutaneous tunnel is then created to bring the stent to the level of the iliac crest. Another tunnel is fashioned to bring the lower end of the stent out suprapubically, followed, finally, by suprapubic puncture of a full bladder and insertion of the lower end (Fig. 59.7).⁸ Extra-anatomic stents are usually changed at 6-month intervals, and preliminary experience confirms their value in maintaining ureteral patency and avoiding PCN. Because of the effectiveness of minimally invasive methods, open surgery today is rarely indicated in the acute setting.

Pelviureteral Junction Obstruction

Until recently, the standard approach to pelviureteral junction obstruction was open surgical pyeloplasty. In recent years, laparoscopic pyeloplasty has emerged as the new gold standard, with success rates equal to those of open pyeloplasty (95%).⁹ Alternatively, pelviureteral junction obstruction can be treated endoscopically, either antegrade (percutaneous endopyelotomy) or retrograde (ureteroscopic endopyelotomy).

Retroperitoneal Fibrosis

Retroperitoneal fibrosis can be treated medically or surgically. A causative factor should be excluded (see Chapter 58). There are reports of favorable outcome after immunosuppression with high doses of corticosteroids or azathioprine. Alternatively, surgery, consisting of ureterolysis and transposition of the ureters into the peritoneal cavity or omental flaps, can have good long-term results.

Malignant Obstruction

For upper tract transitional cell carcinoma, acute obstruction is best treated by internal stenting. PCN is avoided because of the risk of tumor seeding. Upper tract transitional cell carcinoma is an aggressive tumor and necessitates prompt extirpative surgery.

Bladder cancer can lead to hydronephrosis by invading the ureteral orifices and intramural ureter. Radical cystectomy is indicated, although temporary ureteral decompression may normalize renal function if neoadjuvant chemotherapy is planned. In selected cases, bladder preservation strategies combining systemic chemotherapy and radiotherapy can reverse the obstruction and offer long-term control of the disease.

Prostate cancer causes obstruction by occluding the urethra or invading the ureteral orifices. Hormonal treatment can shrink prostatic tissue and malignant deposits and offer long-term remission of symptoms. Limited resection of the prostate may sometimes be indicated.

The decision to offer ureteral decompression for upper tract obstruction due to cancer is not straightforward and requires input not only from the urologist but also from colleagues in radiation and medical oncology and the palliative care team. There must also be careful discussion of the options with the patient and family.

Ureteral decompression is justified when radiotherapy and systemic chemotherapy remain therapeutic options after improvement in renal function but may also be justified for palliation of pain or ongoing renal tract sepsis.

A review of patients undergoing PCN for obstructive uropathy secondary to pelvic malignant disease identified a group of patients with very poor survival in whom ureteral decompression is usually not justified (Fig. 59.8).¹⁰ Patients with gastric or pancreatic cancer survive a median of only 1.4 months after ureteral decompression, calling into question the benefit of such a procedure in this setting.¹¹ In another report, the average survival of patients with advanced malignant neoplasms undergoing endourologic diversion was only 5 months, half of which time was spent in the hospital.¹²

Benign Ureteral Strictures

These can be secondary to stone disease, iatrogenic, or caused by various benign diseases. The treatment of choice is endoscopic balloon dilation or ureterotomy. Open surgical repair or major reconstructive surgery may be needed in cases of recurrent strictures.

Benign Prostatic Hyperplasia

Obstruction, upper tract dilation, and renal impairment due to benign prostatic hypertrophy are indications for surgical treatment. However, if long-term obstruction has severely weakened

Percutaneous Nephrostomy for Malignant Obstructive Uropathy		
	Median Survival (wk)	5-yr Survival Rate (%)
Group I: primary untreated malignancy	27	10
Group II: recurrent malignancy with further treatment	20	20
Group III: recurrent malignancy with no further treatment	6.5	None survived >1 yr
Group IV: benign disease as a result of previous treatment	Not stated	64
Overall	26	22

Figure 59.8 Percutaneous nephrostomy for malignant obstructive uropathy. Outcome in 77 patients undergoing percutaneous nephrostomy for obstructive uropathy secondary to pelvic malignant disease. (Data from reference 10.)

the detrusor muscle, prostatectomy will not restore voiding in up to 50% of cases. These patients will be treated best with intermittent clean self-catheterization or a permanent urethral or suprapubic catheter.

Neurologic Diseases of the Lower Urinary Tract

Diseases of the central or peripheral nervous system can present with bladder underactivity or detrusor-sphincter dyssynergia and lead to bilateral hydroureter and hydronephrosis. Diabetes mellitus can also produce a flaccid denervated bladder through destruction of the peripheral nerves and cause chronic retention and renal failure. Of diabetics who develop peripheral neuropathy, 75% to 100% will develop some neurogenic lower urinary tract dysfunction. The treatment of choice is generally intermittent clean self-catheterization, with a limited role for surgery.

INVESTIGATION OF HEMATURIA

Macroscopic (visible) hematuria is perhaps the most important symptom in urologic practice, and quite apart from being alarming to the patient, it can be the first presenting sign of an underlying malignant condition of the urinary tract (most often a transitional cell tumor of the bladder). Studies show that 15% to 22% of patients with visible hematuria have an underlying genitourinary tract malignant neoplasm.

Patients with macroscopic hematuria must be distinguished from those who have been found to have dipstick hematuria or microscopic hematuria, in whom the risk of malignant change is significantly lower (2% to 11%).

The outcome of full evaluation of a large group of patients (with both macroscopic and microscopic hematuria) attending a hematuria clinic is shown in Figure 59.9.¹³ In addition to a small but important group of patients in whom malignant disease was identified, there was a significant pickup rate of parenchymal renal disease (about 10%), presenting with both macroscopic and microscopic hematuria. It is also important to note the sizable proportion of patients in whom a definitive diagnosis could not be reached.

Outcome of Evaluation in a Hematuria Clinic			
Diagnoses Found	All (%)	Microscopic Hematuria (%)	Macroscopic Hematuria (%)
No diagnosis	1168 (60.5)	670 (68.2)	498 (52.5)
Renal cancer	12 (0.6)	3 (0.3)	9 (0.9)
Upper tract transitional cell carcinoma	2 (0.1)	1 (0.1)	1 (0.1)
Bladder cancer	230 (11.9)	47 (4.8)	183 (19.3)
Prostate cancer	8 (0.4)	2 (0.2)	6 (0.6)
Stone disease	69 (3.6)	39 (4.0)	30 (3.2)
Urinary tract infection	251 (13.0)	128 (13.0)	123 (13.0)
Renal parenchymal disease	190 (9.8)	92 (9.4)	98 (10.3)
Likelihood of Finding Malignancy*			
	Microscopic Hematuria	Macroscopic Hematuria	
Male, age > 40 yr	8	24	
Male, age < 40 yr	1.7 (1 case)	6.5	
Female, age > 40 yr	5.2	19	
Female, age < 40 yr	none	none	

Figure 59.9 Outcome of evaluation in a hematuria clinic. *Percent-age of cases investigated, according to age. (Data from reference 13.)

Evaluation of Macroscopic Hematuria

All adults with a single episode of macroscopic hematuria require full urologic evaluation, including renal imaging and cystoscopy. The only exception to this rule occurs when an adult younger than 40 years gives a history characteristic of glomerular hematuria, such as is typically seen in IgA nephropathy, in which dark brown hematuria lasting 24 to 48 hours coincides with intercurrent mucosal infection, usually of the upper respiratory tract. This hematuria may be painless, or there may be bilateral loin ache. These young adults should be referred first for nephrologic assessment.

Evaluation of Asymptomatic Microscopic Hematuria

The precise definition of microscopic hematuria remains contentious, and it has also been controversial whether these patients should be investigated by a urologist or nephrologist and how patients should be observed if investigation findings are normal.¹⁴

In 2001, the recommendations of the American Urological Association Best Practice Policy Panel on the management of asymptomatic microscopic hematuria in adults were published, providing an evidence-based set of guidelines for family physicians, urologists, and nephrologists in dealing with this condition.¹⁵ Interpretation of the evidence continues to produce controversy about the likelihood of identifying a cause of hematuria.

Microscopic hematuria is common; the prevalence is at least 2% in the general population. It is more common in women and with increasing age (see Chapter 15, Fig. 15.7). There is no evidence to justify screening for microscopic hematuria except in specific high-risk groups, for example, those with occupational

exposure to oncogenic chemicals or dyes (including benzidine and aromatic amines).

The typical definition of microscopic hematuria is three or more red blood cells per high-power field on microscopic evaluation of urinary sediment from two of three properly collected urinalysis specimens. Dipstick-positive hematuria may still herald significant disease in the absence of red cells on microscopy because red cells may lyse in alkaline or hypotonic urine before reaching the laboratory for analysis. Urine microscopy is discussed further in Chapter 4. If a careful history suggests a benign cause of the hematuria, the patient should undergo repeated urinalysis 48 hours after cessation of the implicated activity (i.e., menstruation, vigorous exercise, sexual activity, or trauma). No additional evaluation is warranted if the hematuria has resolved.

Two of three positive test results are sufficient to justify evaluation because intermittent hematuria still carries a significant risk for malignant disease. Full evaluation should still be considered if there is only a single positive test result or if there are only one or two red blood cells per high-power field when there are risk factors for significant disease (Fig. 59.10).

Complete evaluation of microscopic hematuria includes a history and physical examination, laboratory analysis, and radiologic imaging of the upper urinary tract, followed by cystoscopy (see Fig. 59.10). In women, urethral and vaginal examinations should be performed to exclude local causes of microscopic hematuria. In uncircumcised men, the foreskin should be retracted to expose the glans penis, if possible. If a phimosis is present, a catheter specimen of urine may be required. Patients with urinary tract infection should be treated appropriately, and urinalysis should be repeated 6 weeks after treatment. If the hematuria resolves with treatment, no additional evaluation is necessary. Serum creatinine should be measured. The remaining laboratory investigations are guided by specific findings of the history, physical examination, and urinalysis. In some instances, cytologic evaluation of exfoliated cells in the voided urine may also be performed. These American Urological Association guidelines are likely to undergo continuing review. Voided urine cytology is becoming controversial as part of the urologic evaluation of hematuria because most urothelial tumors are detected by other modalities. The role of cystoscopy in the evaluation of low-risk patients is also increasingly debated. There is now evidence to justify avoidance of cystoscopy in women younger than 40 years. However, many authorities still recommend cystoscopy in men younger than 40 years because the risk for bladder cancer, although very small, is higher than in young women. A number of urine tests are now available that claim to be more sensitive than urine cytology.¹⁶ The ultimate aim is to avoid cystoscopy, but as yet none of the tests is sufficiently reliable. Virtual cystoscopy with three-dimensional reconstructions of cross-sectional imaging is also advancing to a level at which it may be an alternative to cystoscopy.

Significant proteinuria (>0.3 g/24 h), red cell casts, predominance of dysmorphic red blood cells in the urine (see Chapter 4), or renal impairment should prompt referral to a nephrologist and evaluation for parenchymal renal disease. When present, red cell casts are virtually pathognomonic of glomerular bleeding, but they are often absent in low-grade glomerular disease. Accurate determination of red blood cell morphology requires inverted phase contrast microscopy. In general, glomerular bleeding is associated with more than 80% dysmorphic red blood cells, and lower urinary tract bleeding is associated with more than 80% normal red blood cells.¹⁷ This assessment is operator dependent. An alternative is to assess urinary red cell size by Coulter counter analysis because dysmorphic red cells are smaller

Evaluation of Asymptomatic Microscopic Hematuria

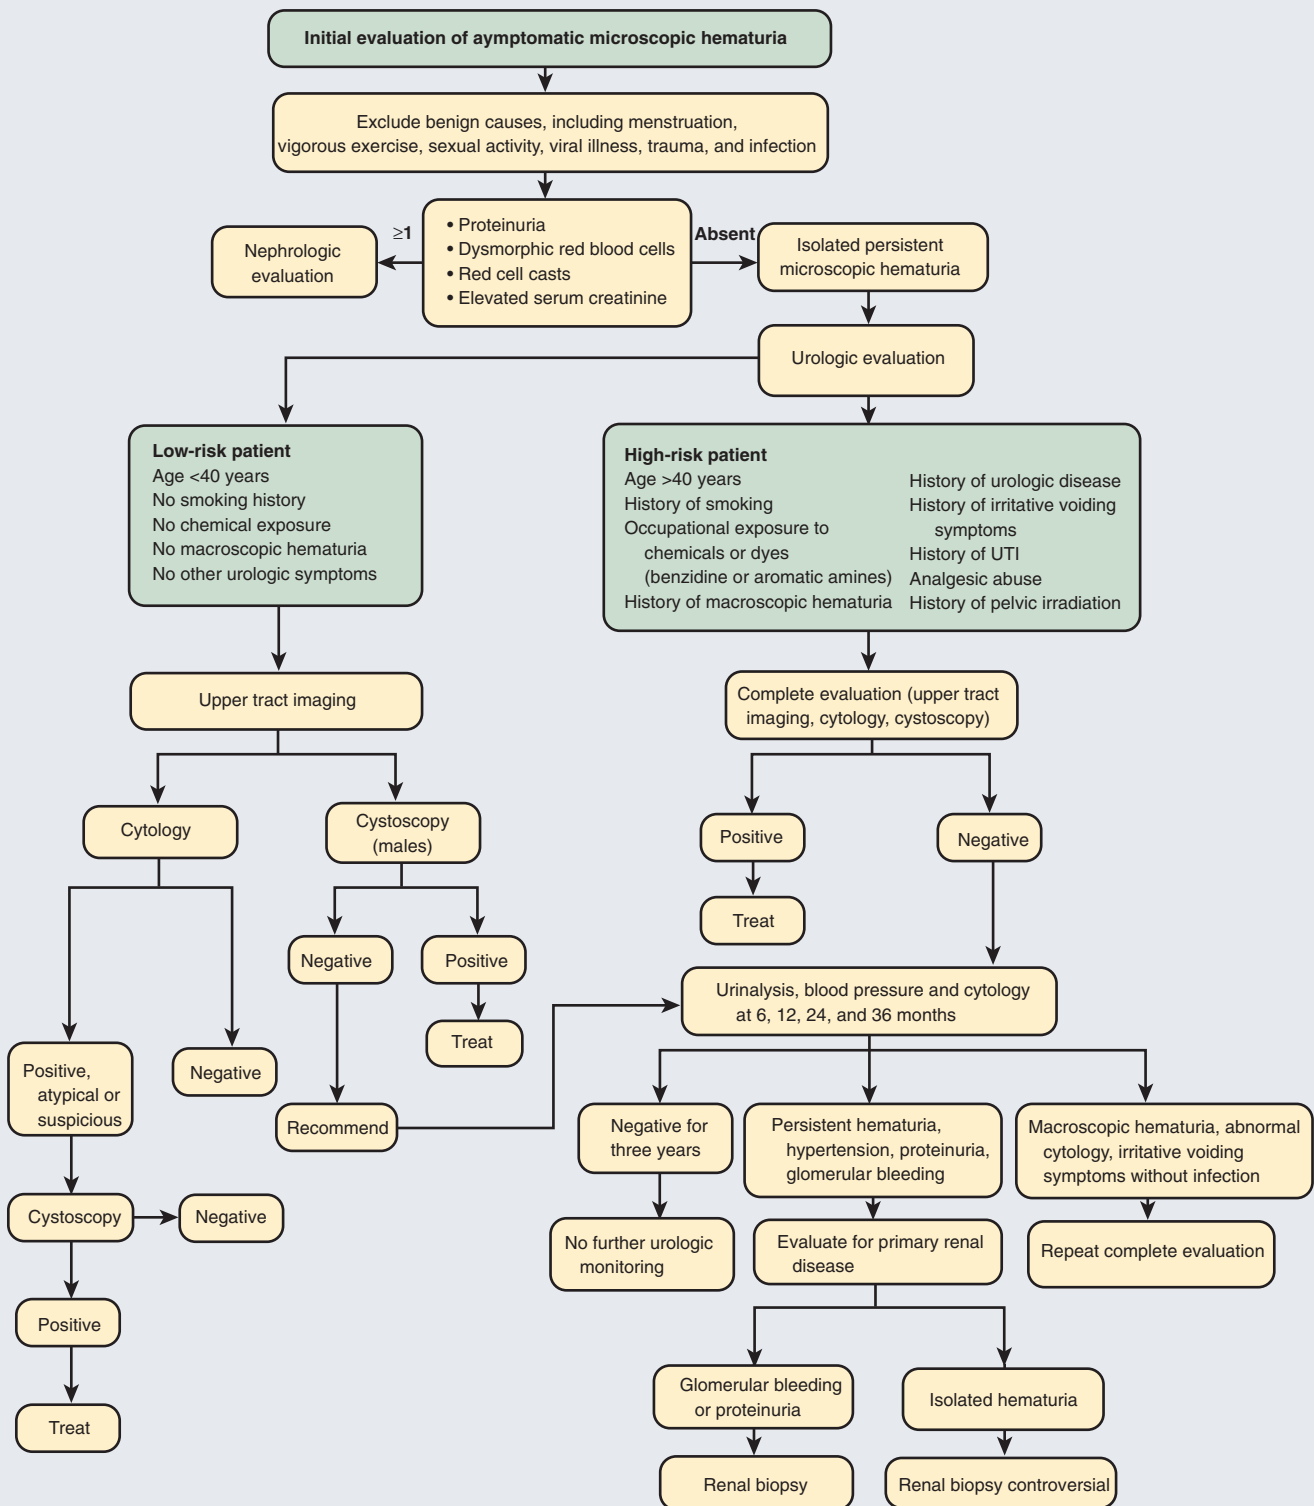

Figure 59.10 Evaluation of asymptomatic microscopic hematuria. UTI, urinary tract infection.

than normal red cells, but this method is not useful when red cell numbers in the urine are small. Even in the absence of features of glomerular bleeding, many patients with isolated microscopic hematuria have glomerular disease, most commonly IgA nephropathy or thin basement membrane nephropathy.¹⁸ Because there is a low risk of progressive renal disease, renal biopsy in this setting is not usually recommended. Nevertheless, one study showed that microscopic hematuria unexplained by urologic evaluation carries a twofold risk for eventual development of ESRD,¹⁹ so these patients should be observed for the development of hypertension, renal impairment, or proteinuria.

Cyclophosphamide

Past treatment with cyclophosphamide increases the risk of bladder cancer up to ninefold, probably in a dose- and duration-dependent manner. Tumors have been reported 6 to 13 years after cyclophosphamide exposure and are often high grade. Hematuria is also common after cyclophosphamide in the absence of cancer. If full evaluation does not identify a cause of hematuria, there is no agreed surveillance protocol; it is not clear whether routine follow-up by cystoscopy and urine cytology is valuable, although a high index of suspicion should be maintained.

INVESTIGATION AND MANAGEMENT OF A RENAL MASS

The incidence of renal cancer has more than doubled in the last 30 years and now accounts for 3% of all cancers. It is the third

most common tumor of the urinary tract but is the most lethal. The apparent increased incidence is partly attributed to the widespread use of cross-sectional imaging; more than 50% of new cases are incidental findings on CT or magnetic resonance imaging (MRI).

The primary goal in investigating a renal mass is to exclude malignancy. Ultrasound has been reported to be 79% sensitive for the detection of renal parenchymal masses but does not detect lesions smaller than 5 mm. Until recently, the gold standard method of assessing renal masses was CT scanning with contrast enhancement, with use of no more than 5-mm slices. MRI, especially with T2-weighted images, may be superior to CT in the correct characterization of benign lesions.²⁰ Choice of imaging techniques and their interpretation are discussed further in Chapter 5.

Any solid mass larger than 3 cm should be regarded as malignant unless the radiologist can be confident that the mass is an angiomyolipoma by the presence of fat on CT images. A biopsy may be required if there is evidence suggestive of an alternative diagnosis (e.g., lymphoma or metastasis from another site) to guide appropriate management. Biopsy, however, has limited value in differentiating between malignant and benign primary renal lesions, mainly because of high false-negative rates.

The management of mixed cystic and solid masses is more of a problem. Figure 59.11 shows the Bosniak classification of cystic renal masses, which has recently been updated.²¹ This classification, based on CT appearances, provides the basis for management according to risk of malignancy. The evaluation of multiple cystic lesions in the kidney is discussed further in Chapter 45.

Classification and Management of Cystic Renal Masses			
Bosniak Class	Features on Imaging	Comment	Management
Class I: simple benign cyst	Round/oval Uniform density <20 H Unilocular No perceptible wall No contrast enhancement	Majority of asymptomatic cystic lesions	No further intervention required
Class II: benign cyst	One or two nonenhancing septa Calcifications in the wall or septum Hyperdense lesions (50-90HU, resulting from the presence of blood, protein, or colloid) < 3cm No contrast enhancement		No further intervention required
Class II F: probable benign cyst	Multiple hairline septa "Perceived" enhancement Nodular calcification Hyperdense lesions >3 cm	"Perceived" enhancement due to contrast within capillaries of septa	Surveillance with CT scans every 6–12 months
Class III: indeterminate cystic lesions	One or more of Thick, irregular borders Irregular calcifications Thickened or enhancing septa Multilocular form Uniform wall thickening Small nonenhancing nodules	About 40% are neoplastic Magnetic resonance imaging may improve characterization	Surgical exploration
Class IV: presumed malignant cystic masses	Appear malignant Heterogeneous cysts Shaggy, thickened walls or enhancing nodules	Appearances result from necrosis and liquefaction of a solid tumor or a tumor growing in the wall	Surgical exploration

Figure 59.11 Classification and management of cystic renal masses. Approach to renal mass found incidentally by ultrasound or CT scanning. All patients with symptomatic renal masses should be referred for urologic assessment. Classification after Bosniak. H, Hounsfield units. (Data from reference 21.)

Tumor size is important; in a large retrospective study of 2935 patients with surgically treated solid renal tumors, 46% of lesions smaller than 1 cm were benign compared with 22% and 10% of tumors 1 to 2 cm and 4 to 5 cm, respectively. Furthermore, only 2.3% of cancers smaller than 1 cm were of high grade, whereas for tumors larger than 7 cm, the percentage was 58%.²² Surveillance studies of small renal tumors have shown a median growth rate of 0.28 cm per year; about 30% of these lesions will not increase in size. Biopsy of a renal mass is frequently nondiagnostic and may render radiographic follow-up more difficult.

The standard of care for localized kidney cancer is radical nephrectomy, open or laparoscopic; 5-year survival approaches 97% for tumors smaller than 4 cm. Partial nephrectomy can provide similarly good results and better preserve renal function. Usual indications for nephron-sparing surgery are an anatomic or functionally solitary kidney and a compromised contralateral kidney, but it can also be performed with a healthy contralateral kidney.

There is a growing trend for minimally invasive treatment of small renal tumors. Radiofrequency ablation and cryotherapy are the modalities most commonly used, and preliminary results show excellent short-term survival and metastasis-free rates, although concerns exist about local recurrence rates. The main disadvantages are that a tissue diagnosis is not always obtained and that radiologic follow-up can be difficult owing to the presence of necrosis and scar tissue. Interestingly, data from the United States show that the development of these newer technologies and the increased detection and treatment of renal tumors have not led to a corresponding decrease in age-specific renal cancer mortality rates.²³

The Natural History of Renal Impairment After Surgical Treatment of Renal Cancer

It is well established that normal renal function can be preserved in the long term after donor transplant nephrectomy. However, donors are highly selected to minimize comorbidities and generally are younger than patients treated of renal tumors. After surgery for suspected renal cancer, when the residual renal mass is small, there is significant risk for late sequelae, including proteinuria, glomerulosclerosis, and progressive renal failure. These risks are greater when radical rather than partial nephrectomy is employed. A retrospective survey studied 662 patients who underwent surgery for a tumor 4 cm or less, with normal preoperative serum creatinine concentration and a normal contralateral kidney on imaging²⁴; 26% of patients had postoperative glomerular filtration rate (GFR) lower than 60 ml/min, and mean GFR was 69 ml/min, significantly lower than reported after donor nephrectomy (92 to 103 ml/min). Postoperatively, the 3-year and 5-year probabilities of freedom from development of GFR below 60 ml/min were 80% and 67% after partial nephrectomy and 35% and 23% for radical nephrectomy. The probabilities of freedom from GFR below 45 ml/min were 95% and 93% after partial nephrectomy and only 64% and 57% for radical nephrectomy at 3 and 5 years postoperatively. Considering the excellent cancer-specific survival (>90%) of patients treated for renal tumors smaller than 4 cm, treatment-induced renal failure may have significant long-term consequences.

In another study, the effect of nephron-sparing surgery on solitary kidneys was assessed in a series of 400 patients.²⁵ Preoperatively, 56% of the patients had serum creatinine concentration above 1.5 mg/dl (136 μ mol/l). Transient renal failure was observed in 21% of patients postoperatively; hemodialysis was

necessary in 3.5%. At a mean follow-up of 44 months, 38% had more than 50% increase in serum creatinine, although only 5% of patients progressed to end-stage renal disease requiring renal replacement therapy. Overall, patients with a congenital single kidney tolerated partial nephrectomy better than did patients with acquired solitary kidneys. Other factors affecting long-term renal function were age and the percentage of parenchyma resected but not the use of hypothermia or the duration of renal ischemia during surgery.

Renal Cell Carcinoma in von Hippel–Lindau Disease

von Hippel–Lindau disease (VHL) is a rare autosomal dominant condition with a predisposition to the development of renal cell carcinoma. The genetics, clinical manifestations, and general management of VHL are discussed further in Chapter 45. The incidence of renal cell carcinoma in VHL is about 45%. On histologic examination, the tumors are of the clear cell type, often multifocal and bilateral, and can be solid or cystic. The mean age at diagnosis is 39 years, and there is a 30% to 35% risk for tumor progression, metastasis, and death.

A serial CT study²⁶ identified 228 renal lesions (on average, 8 per patient) in VHL patients, of which 74% were classified as cysts, 8% as cysts with solid components, and 18% as solid masses. The solid components of cysts and the solid lesions almost always contained renal cell carcinoma. During a mean 2.4-year follow-up (range, 1 to 12 years), most cysts remained the same size (71%) or enlarged (20%), and 9% became smaller. On the contrary, 95% of solid masses increased in size. Although it is generally thought that the cysts are premalignant, the transformation of a simple cyst to a solid lesion was observed in only two patients. VHL patients require multidisciplinary management. Surgical intervention is deferred for tumors smaller than 3 cm because metastasis is rare. In addition, bilateral nephrectomy should be avoided, if possible, because of the substantial morbidity associated with renal replacement therapy. The standard of care for these patients is partial nephrectomy, and 10-year survival rates of 81% have been reported.

The results of nephron-sparing surgery for VHL appear less satisfactory than for sporadic renal cell carcinoma because of a high risk of local tumor recurrence. Repeated surgery may be needed for new or growing lesions, and for this reason the use of minimally invasive methods is being investigated. Repeated ablation of tumors with radiofrequency and cryotherapy is possible with minimal morbidity; however, the long-term effectiveness of these methods has not yet been established.

Acute Interstitial Nephritis

Jerome A. Rossert, Evelyn A. Fischer

DEFINITION

Acute interstitial nephritis (AIN) is an acute, often reversible disease characterized by inflammatory infiltrates within the interstitium. AIN is a rare cause of acute kidney injury (AKI), but it should not be overlooked because it usually requires specific therapeutic interventions.

PATHOGENESIS

Most studies suggest that AIN is an immunologically induced hypersensitivity reaction to an antigen that is classically a drug or an infectious agent. Evidence for a hypersensitivity reaction in drug-induced AIN includes the following: it occurs only in a small percentage of individuals; it is not dose dependent; it is often associated with extrarenal manifestations of hypersensitivity; it recurs after accidental reexposure to the same drug or to a closely related one; and it is sometimes associated with evidence of delayed-type hypersensitivity reaction (renal granulomas). Similarly, AIN secondary to infections can be differentiated from pyelonephritis by the relative absence of neutrophils in the interstitial infiltrates and the failure to isolate the infective agent from the renal parenchyma, again suggesting an immunologic basis to the disease.

Studies of experimental models of AIN have shown that three major categories of antigens can induce AIN.¹ Antigens may be tubular basement membrane (TBM) components (such as the glycoproteins 3M-1 and TIN-Ag/TIN1), secreted tubular proteins (such as Tamm-Horsfall protein), or nonrenal proteins (such as from immune complexes).

Although some types of human AIN may be secondary to an immune reaction directed against a renal antigen, the majority of cases of AIN are probably induced by extrarenal antigens, being produced in particular by drugs or infectious agents. These antigens may be able to induce AIN by a variety of mechanisms. These mechanisms include binding to kidney structures (“planted antigen”); acting as haptens that modify the immunogenicity of native renal proteins; mimicking renal antigens, resulting in a cross-reactive immune reaction; and precipitating within the interstitium as circulating immune complexes.

Studies of experimental models of AIN show that their pathogenesis involves either cell-mediated immunity or antibody-mediated immunity (Fig. 60.1). In humans, most forms of AIN are not associated with antibody deposition, which suggests that cell-mediated immunity plays a major role. This hypothesis is reinforced by the fact that interstitial infiltrates usually contain numerous T cells and that these infiltrates sometimes form granulomas. Nevertheless, deposition of anti-TBM antibodies or of immune complexes can be observed occasionally in renal biopsy

specimens, and antibody-mediated immunity may play a role in the pathogenesis of the disease in these cases.

Formation of immune complexes within the interstitium, or interstitial infiltration with T cells, will result in an inflammatory reaction. This reaction is triggered by many events, including activation of the complement cascade by antibodies and release of inflammatory cytokines by T lymphocytes and phagocytes (see Fig. 60.1). Although the interstitial inflammatory reaction may resolve without sequelae, it sometimes induces interstitial fibroblast proliferation and extracellular matrix synthesis, leading to interstitial fibrosis and chronic renal failure. Cytokines such as transforming growth factor β appear to play a key role in this latter process.

EPIDEMIOLOGY

AIN is an uncommon cause of AKI and is identified in only about 2% to 3% of all renal biopsy specimens.² However, it may account for up to 10% to 25% of patients undergoing renal biopsy for unexplained or drug-induced AKI, respectively.² Although AIN can occur at any age, it appears to be rare in children.

Before antibiotics were available, AIN was most commonly associated with infections, such as scarlet fever and diphtheria. Currently, AIN is most often induced by drugs, particularly antimicrobial agents, proton pump inhibitors, and nonsteroidal anti-inflammatory drugs (NSAIDs). Drug-induced AIN appears to account for about 75% to 90% of all cases.

DRUG-INDUCED ACUTE INTERSTITIAL NEPHRITIS

Clinical Manifestations

In the 1960s and 1970s, most cases of drug-induced AIN were caused by methicillin, and the clinical manifestations of methicillin-induced AIN were considered the prototypical presentation of AIN. Since then, many other drugs have been implicated in the induction of AIN (Fig. 60.2), of which antimicrobial agents (in particular, β -lactam antibiotics, sulfonamides, fluoroquinolones, and rifampin) and NSAIDs (especially fenoprofen) as well as cyclooxygenase 2 (COX-2) inhibitors have been most commonly involved. Anticancer agents, diuretics, phenindione, phenytoin, and allopurinol have also been reported to cause AIN. There are increasing numbers of reports of AIN induced by proton pump inhibitors, with more than 70 reported biopsy-proven cases.³ Recently, cases of drug-induced AIN have also been reported in human immunodeficiency virus (HIV)-infected patients treated with highly active antiretroviral therapy (HAART)⁴ and in cancer patients treated with tyrosine kinase

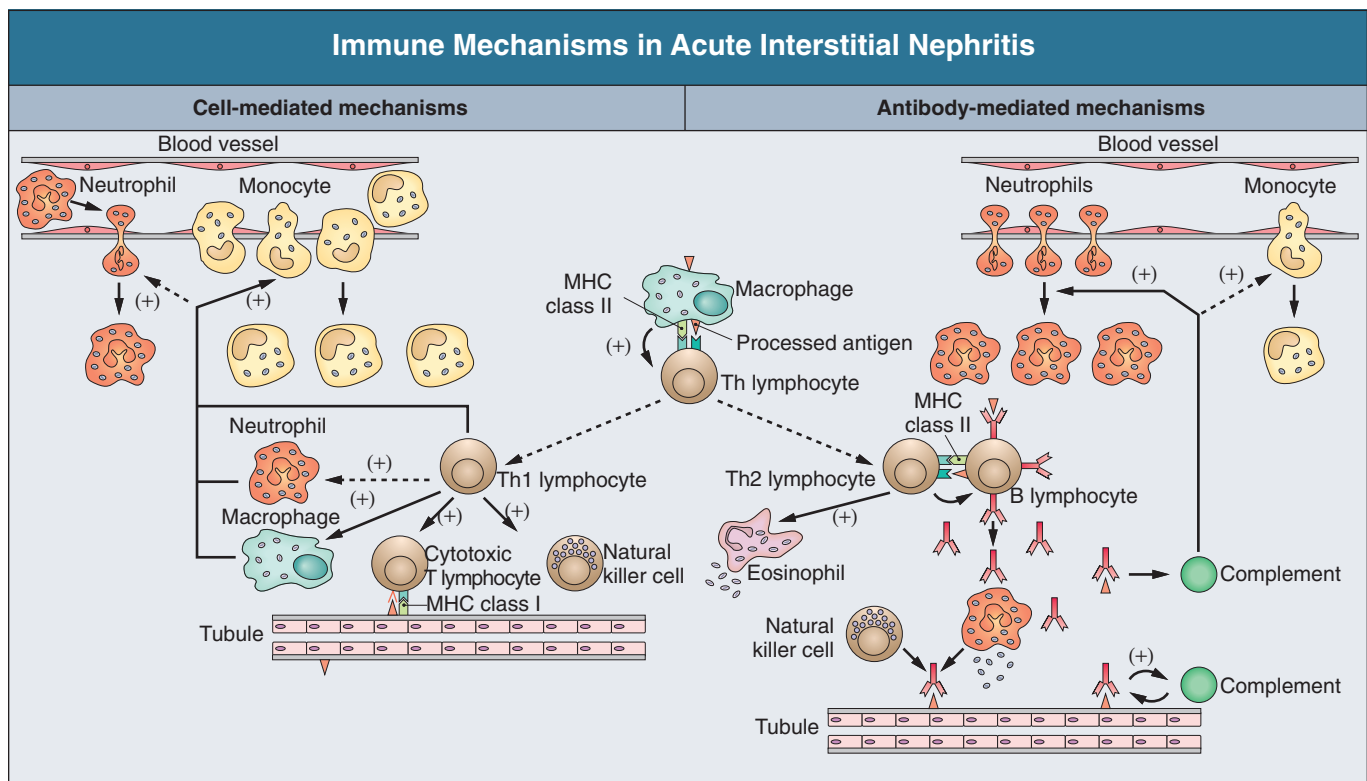

Figure 60.1 Immune mechanisms that can be involved in acute interstitial nephritis. Both cell-mediated and antibody-mediated mechanisms occur. The cell-mediated mechanism is primarily associated with macrophages and T cells. The antibody-mediated mechanism is frequently associated with neutrophil or eosinophil infiltration as well as with local complement activation. MHC, major histocompatibility complex.

inhibitors.⁵ Most other drugs have only rarely been linked with AIN (see Fig. 60.2). The clinical characteristics of drug-induced AIN are now recognized as much more varied and nonspecific than the spectrum seen in classic methicillin-induced AIN (Fig. 60.3).^{6,7}

Renal Manifestations

Symptoms of AIN usually develop a few days to a few weeks after the inciting drug is started, although cases have occurred months after initial exposure to the drug. The typical presentation is sudden impairment in renal function, associated with mild proteinuria (<1 g/day) and abnormal urinalysis, in a patient with flank pain, normal blood pressure, and no edema. In patients with AIN not caused by methicillin, the clinical presentation is often incomplete (see Fig. 60.3), and AIN should be considered in any patient with unexplained AKI.^{6,7} The renal dysfunction may be mild or severe; dialysis is required in about one third of patients. Hematuria and pyuria are present in a little more than half of the patients, and although leukocyte casts are common, hematuria is almost never associated with red blood cell casts. Flank pain, reflecting distention of the renal capsule, is observed in about one third of the patients and can be the main complaint on hospital admission. On occasion, patients have a low fractional excretion of sodium.

Standard imaging procedures show kidneys normal in size or slightly enlarged. Ultrasound usually discloses an increased cortical echogenicity (comparable to or higher than that of the liver).

Extrarenal Manifestations

Extrarenal symptoms consistent with a hypersensitivity reaction are occasionally observed, including low-grade fever, maculo-

popular rash (Fig. 60.4), mild arthralgias, and eosinophilia. If patients with methicillin-induced AIN are not considered, each of these symptoms is present in less than half of the patients (see Fig. 60.3), and all these symptoms are present together in less than 10% of patients.^{2,6,7} With some drugs, other manifestations of hypersensitivity, such as hemolysis or hepatitis, can be present. Serum IgE levels may also be elevated.

The association of AKI either with clinical signs suggestive of hypersensitivity or with eosinophilia should lead to consideration of a diagnosis of AIN. However, signs of hypersensitivity can also be observed in patients with AKI not related to AIN, including patients with drug-induced acute tubular necrosis.

Other Specific Drug Associations

The clinical and biologic manifestations of AIN may have some specificity, depending on the drug involved.

As outlined earlier, methicillin-induced AIN is characterized by a high frequency of abnormal urinalysis and extrarenal symptoms and by good preservation of renal function. Renal failure has been reported in only about 50% of patients (see Fig. 60.3).

More than 200 cases of rifampin-induced AKI have been reported. Most have been observed either after readministration of rifampin or several months after intermittent administration of the drug. Renal failure is usually associated with the sudden onset of fever, gastrointestinal symptoms (nausea, vomiting, diarrhea, abdominal pain), and myalgias. It may also be associated with hemolysis, thrombocytopenia, and less frequently hepatitis. Renal biopsy typically discloses tubular injury in addition to interstitial inflammatory infiltrates. Although circulating anti-rifampin antibodies are usually found in these patients, immunofluorescence staining of renal biopsy specimens has been

negative in most cases, suggesting that cell-mediated immunity plays a key role in the induction of the nephritis. In a few cases, AIN developed after continuous treatment with rifampin for 1 to 10 weeks. It was almost never associated with extrarenal symptoms or with anti-rifampin antibodies, and renal biopsy specimens showed severe interstitial infiltrates but few tubular lesions.

Phenindione-induced AIN is generally associated with the development of hepatitis, which can be fatal.

Allopurinol-induced AIN appears to occur more often in patients with chronic kidney disease (CKD) and is usually seen in association with rash and liver dysfunction. It has been suggested that the decreased excretion of oxypurinol, a metabolite of allopurinol, might favor the occurrence of AIN. There is also

Figure 60.3 Clinical manifestations of drug-induced acute interstitial nephritis. Data were pooled from different case reports, including 95 patients with methicillin-induced AIN and more than 200 patients with other drug-induced AIN. Patients with AIN associated with a nephrotic syndrome are not included.

some experimental evidence that in the setting of renal impairment, allopurinol may precipitate as microcrystals or crystals and cause direct nephrotoxicity. Whether this can occur in humans is unknown, but it may provide an additional reason to reduce allopurinol doses in subjects with CKD.

AIN occurring secondary to NSAIDs is associated with nephrotic syndrome in about three fourths of cases. This usually occurs in patients older than 50 years, and although it has been observed with all NSAIDs, including COX-2-selective inhibitors, half of the incidents have been reported with fenoprofen. Most occurrences develop after the patient has taken NSAIDs for some months (mean, 6 months), but AIN can occur within days or after more than a year. With the exception of the heavy proteinuria and associated edema, the presentation of these patients is similar to that of patients with other drug-induced AIN (Fig. 60.5). The main difference is that extrarenal symptoms are present in only about 10% of patients. Renal disease caused by NSAIDs must be differentiated from other NSAID-induced nephropathies, including hemodynamically mediated AKI, papil-

Figure 60.4 Maculopapular rash in a patient with drug-induced acute interstitial nephritis. Such cutaneous lesions occur in about 40% of patients with drug-induced AIN, but they can also be seen in patients with drug-induced acute tubular necrosis.

Figure 60.5 Clinical presentation of AIN and nephrotic syndrome associated with NSAID use. Data were pooled from different case reports from more than 60 patients.

lary necrosis, and NSAID-induced membranous nephropathy. Drugs other than NSAIDs can rarely induce AIN associated with a nephrotic syndrome; a few cases have been reported after administration of ampicillin, rifampin, lithium, interferon, phenytoin, pamidronate, and D-penicillamine.

Pathology

The hallmark of AIN is the presence of inflammatory infiltrates within the interstitium (Fig. 60.6). These infiltrative lesions are often patchy, predominating in the deep cortex and in the outer medulla, but they can be diffuse in severe cases. They are composed mostly of T cells and monocytes-macrophages, but plasma cells, eosinophils, and a few neutrophilic granulocytes may also be present. The relative number of CD4⁺ T cells and CD8⁺ T cells is variable from one patient to another. In some cases, T lymphocytes infiltrate across the TBM and between tubular cells, mainly in distal tubules, and the resulting lesion is referred to as tubulitis.

In some cases of drug-induced AIN, renal biopsy shows interstitial granulomas (Fig. 60.7). These granulomas are usually sparse and non-necrotic, with few giant cells, and are associated with nongranulomatous interstitial infiltrates. Granulomas are also found in AIN related to infection (see Fig 60.10), sarcoidosis, Sjögren's syndrome, and Wegener's granulomatosis.

Interstitial infiltrates are always associated with an interstitial edema, which is responsible for separating the tubules (see Fig. 60.6). They can also be associated with focal tubular lesions, which range from mild cellular alterations to extensive necrosis of epithelial cells and are sometimes associated with a disruption of the TBM. These tubular lesions usually predominate where the inflammatory infiltrates are most extensive.

Figure 60.6 Drug-induced acute interstitial nephritis. On light microscopy, the characteristic feature is interstitial infiltration with mononuclear cells, with normal glomeruli. It is usually associated with interstitial edema and tubular lesions. (Courtesy of Dr. B. Mougenot, Paris VI University, Paris France.)

Figure 60.7 Drug-induced granulomatous acute interstitial nephritis. Some drugs can induce the formation of interstitial granulomas, which reflect a delayed-type hypersensitivity reaction. (Courtesy of Dr. B. Mougenot, Paris VI University, Paris France)

Tubulointerstitial lesions are not associated with vascular or glomerular lesions. Even in AIN associated with a nephrotic syndrome, glomeruli appear normal on light microscopy; glomerular lesions are similar to those seen in minimal change disease (see Chapter 17).

In most patients with AIN, renal biopsy specimens do not show immune deposits, and both immunofluorescence and electron microscopy are negative. Nevertheless, staining of the tubular or capsular basement membrane for IgG or complement may occasionally be seen by immunofluorescence; the staining pattern is either granular or linear (Fig. 60.8). Linear fixation of IgG along the TBM indicates the presence of antibodies directed against membrane antigens or against drug metabolites bound to the TBM, and circulating anti-TBM antibodies have been detected in some cases. These linear deposits are seen mostly in patients taking methicillin, NSAIDs, phenytoin, or allopurinol.

Diagnosis

The most accurate way to diagnose AIN is by renal biopsy. However, both eosinophiluria and gallium scanning have been suggested as helpful in making the diagnosis.

Eosinophils can be detected in urine with use of either the Wright stain or the Hansel stain, which both are eosin–methylene blue combinations, but the Hansel stain appears to be much more sensitive.^{8,9} The result of this test is usually considered positive if more than 1% of urinary white blood cells are eosinophils. However, although eosinophiluria is frequently used to corroborate the diagnosis of drug-induced AIN, review of four large series shows that this test has rather poor sensitivity (67%) and a low positive predictive value, even when only patients with AKI are considered (50%) (Fig. 60.9).^{8–11} In these series, the specificity of the test was 87%, and eosinophiluria was also observed in patients with acute tubular necrosis, postinfectious or crescentic glomerulonephritis, atheroembolic renal disease, urinary tract infection, urinary schistosomiasis, and even pre-renal AKI. In particular, 28% of patients with urinary tract infection had eosinophiluria. Because of these limitations, eosinophiluria should no longer be used as a screening test.

An increased renal uptake of gallium 67 has been reported in AIN.¹² Analysis of available series shows that in 45 patients with AIN, 88% had an abnormal renal scan (maximum after 48 hours),

Figure 60.8 Linear deposits of IgG in methicillin-induced acute interstitial nephritis. Deposits along the TBM are shown on immunofluorescence microscopy. These antibodies recognize either a component of the TBM or a methicillin metabolite (dimethoxyphenylpenicilloyl) bound to the TBM. (Courtesy of Dr. B. Mougenot, Paris VI University, Paris France.)

Figure 60.9 Eosinophiluria in the diagnosis of acute interstitial nephritis. The four large available series were analyzed to assess the value of eosinophiluria (defined by the presence of >1% of eosinophils in urine) for the diagnosis of drug-induced AIN. Only 67% of AIN was associated with eosinophiluria, whereas 13% of non-AIN was associated with eosinophiluria.

Eosinophiluria and the Diagnosis of Acute Interstitial Nephritis

No eosinophiluria	8	41	82	17	148 (89%)

whereas it was normal in 17 of 18 patients with acute tubular necrosis. However, these studies were small and retrospective, and gallium 67 renal scanning is not specific for AIN and may be abnormal in patients with pyelonephritis, cancer, or glomerular diseases. Therefore, we also do not recommend use of gallium scanning as a diagnostic tool.

Because the clinical presentation of AIN may be polymorphic and because noninvasive diagnostic procedures have important limitations, renal biopsy is often essential for the diagnosis of AIN. Several studies have shown that prebiopsy diagnosis may be incorrect in a substantial number of patients.

Identification of the Causative Drug

Identification of the causative drug is relatively easy when AIN occurs in a patient taking only one drug. However, patients are often taking more than one drug capable of inducing AIN. Two biologic tests have been used, primarily in research laboratories, to help identify the causative drug: the lymphocyte stimulation test and the identification of circulating antidrug antibodies.

Identification of circulating antidrug antibodies has been used mostly for patients thought to have AIN induced by rifampin. Anti-rifampin antibodies are present in most patients with rifampin-induced AIN; but unfortunately, they have also been detected in patients taking rifampin and having no adverse reaction to the drug, so this test has a limited diagnostic value.

The lymphocyte stimulation test has been used since the 1960s to identify a sensitizing drug. It is based on the measurement of lymphocyte proliferation in the presence of different drugs; a high proliferative index reflects a sensitization of T lymphocytes against the drug. However, this test lacks specificity and we do not recommend using it.

Natural History

Drug-induced AIN was long considered benign, with complete recovery of renal function if the inciting agent was removed. For

example, with methicillin-induced AIN, a complete normalization of serum creatinine has been observed in about 90% of uremic patients. Nevertheless, although hematuria, leukocyturia, and extrarenal symptoms usually disappeared within 2 weeks, complete recovery of renal function was often delayed, with an average recovery time of about 1.5 months.

More recent studies show that with drugs other than methicillin, the course of AIN is not always benign and that serum creatinine remains elevated in about 40% to 50% of patients.^{6,13} Moreover, as for methicillin, recovery of renal function can be delayed, and an increase in serum creatinine can persist for several weeks. Unfortunately, few prognostic factors are available. The severity of renal failure does not appear to be linked with the prognosis.⁶ It has been suggested that the presence on renal biopsy of diffuse neutrophil- or macrophage-rich infiltrates, interstitial granulomas, or tubular atrophy is associated with a poor prognosis, but this has not been consistently found in all series. The best prognostic factors may actually be the duration of AKI and the severity of interstitial fibrosis.

Treatment

In addition to removal of the inciting agent, corticosteroids have been used to treat AIN. Most commonly, patients received an initial daily dose of 1 mg/kg prednis(ol)one, which is then tapered during about 1 month; this oral therapy is sometimes associated with pulses of methylprednisolone. Analysis of series comparing patients who did or did not receive corticosteroids does not allow firm conclusion about the effect of corticosteroid therapy on long-term renal function, all the series being small, uncontrolled, and retrospective. However, some authors advocate an early and systematic use of a short course of corticosteroids.^{7,13} In addition, it seems that a brief course of corticosteroids can hasten the recovery of renal function. In different series, corticosteroids rapidly induced a reduction in serum creatinine in patients whose renal function did not improve within about 1 week after discontinuation of the inciting agent. Interestingly, in patients with

NSAID-induced AIN, corticosteroids do not seem to modify the course of the nephrotic syndrome.

On the basis of anecdotal case reports, some authors have also advocated use of mycophenolate mofetil in patients resistant to corticosteroids.¹⁴

We recommend administration of a short course of prednis(ol)one in patients who are dialysis dependent or whose renal function fails to improve rapidly within 1 week after discontinuation of the inciting drug and return to baseline values, provided the diagnosis of AIN has been confirmed by renal biopsy. We initiate the treatment with 1 mg/kg per day of prednis(ol)one, and after 1 to 2 weeks, we progressively taper the dose so that the total duration of treatment is 4 to 6 weeks.

ACUTE INTERSTITIAL NEPHRITIS SECONDARY TO INFECTIOUS DISEASES

Infections were once the most common cause of AIN, but the frequency of AIN induced by an infection has dramatically decreased with the widespread use of antibiotics. Nevertheless, the diagnosis of infectious AIN should not be overlooked, and AIN occurring in patients treated with antibiotics should not always be attributed to the drug.

Infectious agents can cause renal parenchymal inflammation by direct infection, resulting in acute pyelonephritis (see Chapter 51). However, many infectious agents may also induce an immunologically mediated AIN in the absence of direct invasion (Fig. 60.10). In this case, the clinical presentation depends mostly on the underlying infection. On histologic examination, lesions are identical to those described for drug-induced AIN, and they can also occasionally result in granulomas (see Fig. 60.10). Infection-associated AIN usually resolves with the treatment of the underlying infection, and corticosteroid therapy is not recommended.

An important cause of infection-associated AIN is hantavirus.¹⁵ Hantavirus infections occur worldwide and are responsible for a disease that has been known as hemorrhagic fever with renal syndrome, epidemic hemorrhagic fever, or nephropathia epidemica. Rodents are the main reservoir of the virus, and humans are most probably infected by the airborne route. Extrarenal symptoms usually include fever, headache, lightheadedness, abdominal pain, nausea and vomiting, and thrombocytopenia; the last can be responsible for hemorrhagic complications. AKI is almost always associated with proteinuria, sometimes in the nephrotic range, and with hematuria. When a kidney biopsy is performed, it discloses not only interstitial inflammatory infiltrates, which predominate in the medulla, but also vascular congestion and interstitial bleeding (Fig. 60.11). In about 50% of the patients, immunofluorescence studies show granular immune deposits along the TBM and within glomeruli. Serum creatinine concentration usually starts to decrease after a few days, and a complete recovery of renal function is the rule. Nevertheless, in the more severe cases, recovery can be complicated by the occurrence of hemorrhagic complications or severe shock. The diagnosis is based on serologic test results, which become positive early (within weeks) in the course of the disease.

Tubulointerstitial lesions are common in HIV-positive patients who undergo a renal biopsy for AKI. Interstitial infiltrates are often associated with glomerular lesions, but they can also be isolated. These forms of AIN have been observed in both white and black patients, and they might be related not only to drugs and opportunistic infections but also to the HIV infection itself.¹⁶

ACUTE INTERSTITIAL NEPHRITIS ASSOCIATED WITH SYSTEMIC DISEASES

Sarcoidosis

In sarcoidosis, renal impairment usually occurs as a complication of hypercalciuria and hypercalcemia, but granulomatous AIN associated with sarcoidosis has also been reported (Fig. 60.12).^{17,18} The presentation is usually that of AKI, which can be isolated or associated with mild proteinuria and sterile leukocyturia. It is

Figure 60.12 Granulomatous acute interstitial nephritis in a patient with sarcoidosis. (Courtesy Dr. B. Mougenot, Paris VI University, Paris France.)

associated with extrarenal symptoms of sarcoidosis in about 90% of patients, most frequently with lymphadenopathy and lung, eye, or liver involvement. Nevertheless, only slightly more than half of the patients have hilar lymphadenopathy or pulmonary interstitial fibrosis at the time of diagnosis.¹⁹ Treatment with high-dose corticosteroids quickly improves renal function, but most patients do not recover completely. The starting dose should be 1 mg/kg prednis(ol)one daily, and corticosteroid therapy should be tapered slowly and not withdrawn before at least 1 year to prevent relapses. Whereas some authors advocate long-term maintenance therapy with low-dose corticosteroids, we usually stop corticosteroids after 2 to 3 years. Because of the risk of late relapse, these patients should be observed for a prolonged time.

Sjögren's Syndrome

Clinically significant interstitial nephritis is rare in Sjögren's syndrome and usually results in chronic tubular dysfunction.²⁰ Some patients may present with severe symptomatic hypokalemia with distal renal tubular acidosis. Rarely, Sjögren's syndrome presents with AKI due to AIN. In these patients, treatment with high-dose corticosteroids may dramatically improve renal function.

Systemic Lupus Erythematosus

About two thirds of renal biopsies performed in patients with systemic lupus show some tubulointerstitial involvement, but significant tubulointerstitial injury in the setting of minimal glomerular abnormalities is rare, with only about 10 cases reported in the literature.²¹ In these cases, renal biopsy shows typical features of AIN on light microscopy, and immunofluorescence staining always discloses immune deposits along the TBM, usually with a granular pattern. Renal function improves after high-dose corticosteroids and does not usually require additional immunosuppressive drugs. However, azathioprine has been used as a corticosteroid-sparing agent.

Other Systemic Diseases

Among patients with cryoglobulinemia and AKI, a few exhibit significant interstitial inflammatory infiltrates associated with granular immune deposits in the interstitium and along the TBM. This AIN is usually associated with characteristic glo-

merular lesions and rarely lesions of the arterioles, and treatment is the same as for cryoglobulinemia-induced glomerulonephritis (see Chapter 21).

Most renal lesions associated with small-vessel vasculitis (such as Wegener's granulomatosis) consist of both an extracapillary glomerulonephritis and a tubulointerstitial nephritis. Nevertheless, a few patients with AIN and minimal glomerular lesions have been described.

ACUTE INTERSTITIAL NEPHRITIS ASSOCIATED WITH MALIGNANT NEOPLASMS

Infiltration of renal parenchyma by malignant cells is common in patients with leukemia or lymphoma. Most of the time, this infiltration is totally asymptomatic or only causes enlarged kidneys, but a few patients with AKI have been described.²² Chemotherapy or radiotherapy may rapidly improve renal function in these patients, but before these treatments are started, it is important to exclude more common causes of AKI associated with neoplastic diseases (see Chapter 66).

IDIOPATHIC ACUTE INTERSTITIAL NEPHRITIS

More than 50 cases of idiopathic AIN with anterior uveitis have been reported (TINU syndrome).²³ This syndrome is found most commonly in girls of pubertal age but can also occur in pubertal boys and in adults. Initial symptoms may be ocular, with ocular pain and visual impairment, or pseudoviral, with fever, myalgia, and asthenia. AIN is responsible for AKI, ranging from mild to severe, that may or may not be associated with abnormal urinalysis. Renal biopsy shows diffuse interstitial inflammatory infiltrates, almost always without granulomas and without immune deposits. In children, renal prognosis is excellent, and serum creatinine usually returns to baseline values within a few weeks, with or without corticosteroid therapy. In adults, the renal prognosis seems to be less favorable, and corticosteroid therapy might be useful in preventing evolution to chronic renal failure. Uveitis, which can occur at any time in respect to AIN, is usually responsive to topical corticosteroids, but it may relapse without any recurrence of AIN.

A few cases of idiopathic AIN have been reported. Immunofluorescence studies of renal biopsy specimens can show linear deposits of IgG along the TBM, granular deposits of IgG along the TBM, or no immune deposits, suggesting that this entity is heterogeneous. The treatment of patients with idiopathic AIN is still controversial. Patients who receive corticosteroids usually show a dramatic improvement of renal function, but others have recovered normal renal function without any treatment.

ACUTE INTERSTITIAL NEPHRITIS IN RENAL TRANSPLANTS

Acute rejection is by far the most common cause of AIN in renal allograft recipients (see Chapter 100). Nevertheless, AIN can also be induced by drugs or infections. Cases of drug-induced AIN have been reported even in the first weeks after transplantation, when immunosuppression is maximal.²⁴ Among infectious AIN, the frequency of polyomavirus-induced AIN appears to be increasing, and it should be suspected in patients with acute deterioration of renal function and so-called decoy cells in urine (see Chapter 101).²⁵

Primary Vesicoureteral Reflux and Reflux Nephropathy

Ranjiv Mathews, Tej K. Mattoo

DEFINITION

Vesicoureteral reflux (VUR) is a congenital or hereditary abnormality in which there is retrograde flow of urine from the bladder to the kidneys. This retrograde flow of urine, although normal in some animals, is not normal in humans. VUR may be an isolated abnormality (primary VUR) or may occur with other congenital anomalies of the kidney and urinary tract, including renal dysplasia, obstructive uropathy, and neurogenic bladder (secondary VUR).

VUR is usually identified by fetal ultrasound in pregnancy (in which renal pelvis dilation is observed) or after urinary tract infection (UTI) in childhood. It is commonly believed that the presence of VUR increases the risk of UTI, and the two together can cause renal injury leading to a contracted, scarred kidney termed reflux nephropathy. Reflux nephropathy may present as a UTI, hypertension, toxemia of pregnancy, chronic kidney disease (CKD), and even end-stage renal disease (ESRD). Whereas reflux nephropathy involves primary injury to the renal parenchyma, some subjects also have proteinuria due to secondary focal segmental glomerulosclerosis (FSGS).

Traditional management includes prompt treatment of UTI and long-term antimicrobial prophylaxis until the resolution of VUR. Surgical correction of the VUR may be recommended in those with high-grade VUR who have recurrent UTI in spite of antimicrobial prophylaxis or are noncompliant with medical management. Debate persists on the superiority of one intervention over the other; most studies have concluded that long-term outcomes are similar.

CLASSIFICATION

VUR is classified by radiologic evaluation on voiding cystourethrography (VCU) into five grades as defined by the International Reflux Study in Children (Figs. 61.1 and 61.2).¹ Grade I is reflux into the ureter; grade II is reflux into the renal pelvis, without any dilation of the calyces; grade III is reflux to the renal pelvis with mild dilation of the renal pelvis; grade IV is reflux to the renal pelvis with greater dilation of the renal pelvis; and grade V is reflux to the renal pelvis with ureteral and pelvic dilation. An example of grade V reflux is shown in Figure 61.3.

Grading of VUR is used to predict the outcomes of children with VUR. Because VUR may resolve spontaneously, grading is used to standardize management strategies as well as to compare clinical outcomes between institutions. Although it is widely

used, the classification system is not perfect. Differences between grade III and grade IV are not always obvious. The degree of reflux may be modified by how aggressively the bladder is filled. Ureteral dilation may also be present without calyceal dilation, leading to difficulties with grading.

EPIDEMIOLOGY

VUR is often first suggested by dilation of the fetal kidney during ultrasound examination. VUR is suspected when the fetal renal pelvis is more than 5 mm in anteroposterior diameter; a diameter of more than 10 mm is associated with high-grade VUR. In neonates who had evidence of fetal dilation, as many as 13% to 22% will have VUR by VCU. Indeed, it is estimated that 1% to 2% of healthy children will have VUR, with a higher frequency in boys and premature infants.² The incidence of renal dysplasia is also greater in male infants with VUR.³ Most cases associated with grades I to III VUR will spontaneously resolve within the first year of life, whereas grades IV and V are more likely to persist. Spontaneous resolution of VUR is greater in male infants.

VUR is also diagnosed in 30% to 40% of children presenting with UTI, predominantly girls. VUR is both less common and less severe in African American children.^{4,5} Only about one third as many African American as Caucasian girls with UTI have VUR, and no significant differences in age or mode of presentation exist between the two races.

Reflux nephropathy may be responsible for up to 10% of ESRD and is one of the common causes of ESRD in children. In children, reflux nephropathy occurs equally in boys and girls; in adults, there is a slight female predominance.

ETIOLOGY AND PATHOGENESIS

Primary VUR is a congenital anomaly of the ureterovesical junction, probably due to a preexisting anatomic abnormality with shortening of the intravesical submucosal length of the ureter, leading to an incompetent valve (Fig. 61.4). The formation of the ureteral bud from the mesonephric duct signals the initial development of the metanephric kidney, the final stage of renal development. The ureteral bud interacts with the mesenchyme to give rise to the metanephric kidney. As the mesonephric duct is gradually absorbed into the enlarging urogenital sinus (the precursor of the developing bladder), the location of the ureteral bud plays a role in the eventual location of the ureteral meatus within the bladder. If the ureteral bud reaches the urogenital

Figure 61.1 Grades of VUR.

International Reflux Study in Children Classification of VUR	
Grade	Degree of VUR
I	Ureter only
II	Reflux into ureter, pelvis, and calyces with no dilation and with normal calyceal fornices
III	Mild or moderate dilation and/or tortuosity of the ureter and mild or moderate dilation of the pelvis; no or slight blunting of the fornices
IV	Moderate dilation and/or tortuosity of the ureter, and moderate dilation of the pelvis and calyces; complete obliteration of the pelvis and calyces; complete obliteration of the sharp angles of the fornices but maintenance of the papillary impressions in the majority of the calyces (see Fig. 61.12C)
V	Gross dilation and tortuosity of the ureter, pelvis, and calyces; the papillary impressions are no longer visible in the majority of calyces (see Fig. 61.3)

Figure 61.2 Classification of VUR. The International Reflux Study in Children classification.

Figure 61.3 Gross VUR and intrarenal reflux. A voiding cystourethrogram shows grade V VUR with intrarenal reflux into several renal lobes in an infant.

sinus too early because of the absorption pattern of the mesonephric duct, it is eventually located more laterally and proximally in the bladder. This location is associated with the development of reflux as there is reduction in the intravesical submucosal length of the ureter.

Multiple genes are involved in the development of VUR. *PAX2* (necessary for ureteral budding in mice), glial-derived neurotrophic factor (*GDNF*), angiotensin II type 2 receptor, and uroplakin 3 (which is a component of tight junctions in uroepithelial cells) have been implicated in the development of VUR in mice; however, their role in human VUR remains

controversial.^{6,7} Neither autonomic innervation nor histology of the ureterovesical junction is different between subjects with VUR and controls.⁸

The ureterovesical junction is designed to prevent free reflux of urine from the bladder to the kidney. The ureters pass into the bladder through the detrusor in an oblique path. The distal end of the ureter is located submucosally within the bladder. The length of the submucosal ureter is critical in the prevention of VUR. The muscles of the ureter extend into the trigone of the bladder and mesh with the fibers from the opposite ureter. This intermingling of fibers helps anchor the ureters into the trigone

of the bladder. The distal submucosal segment is compressed against the muscular bladder wall with bladder filling, acting as an additional mechanism to prevent reflux. Because urine is propelled antegrade down the ureter, the tone of the ureter and the meatus in the bladder also help prevent reflux.

Reflux Nephropathy

Reflux nephropathy is thought to result from one of two processes (Fig. 61.5). In some subjects, especially males, renal injury may be due to severe VUR that is associated with renal dysplasia (congenital form). In these subjects, renal injury may occur in the absence of infection. These cases are more commonly seen in boys with grade IV or V VUR, and these children are most commonly identified with the antenatal discovery of renal dilation during fetal ultrasound. The second mechanism for development of reflux nephropathy is likely due to the combination of VUR and repeated UTI that occurs mostly before the age of 5 years (acquired form). In these children, who are more commonly female, the combination of upper tract infection and reflux causes permanent scarring.

In both conditions, the damage to the kidney is likely to be greatest in children younger than 2 years, particularly in those

with severe VUR.⁹ Renal injury is more common in this age group because of delay in diagnosis of UTI due to the non-specific clinical presentation, the difficulties in obtaining urine specimens, and the higher prevalence and severity of VUR in smaller children.

Infection is not always required for the development of reflux nephropathy. Boys probably have primary, congenital, VUR-associated renal damage more commonly, whereas girls have acquired scarring related to recurrences of febrile UTI.¹⁰ Indeed, renal parenchymal defects may occur in children with severe VUR diagnosed during follow-up for antenatal hydronephrosis who have no history of UTI. Furthermore, some siblings with severe VUR have evidence of renal scarring in the absence of documented UTI. Renal damage ascribed to VUR and UTI has also been found to be due to dysplastic changes in the kidney that would be more consistent with congenital renal dysplasia and VUR as the primary underlying cause. Finally, renal scarring as shown by technetium Tc 99m dimercaptosuccinic acid (DMSA) scan correlates more closely with the severity of VUR than with a history of UTI.¹¹ Thus, many subjects with reflux nephropathy probably have renal injury not from previous UTIs but rather from preexisting renal injury, such as from renal dysplasia and injury associated with severe VUR.

PATHOLOGY

The process of renal scarring may take several years; in one study, the mean time from discovery of VUR to the appearance of a renal scar was 6.1 years.¹² Grossly, the injury favors the renal poles and is associated with clubbed calyces with medullary and cortical damage. The injury results from the local inflammatory response that may persist with chronic inflammation, tubular injury, local fibroblast activation, and interstitial collagen deposition (Fig. 61.6).¹³ The loss of nephrons is associated with hyperfiltration and hypertension that result in proteinuria and progressive loss of renal function. This can also lead to the development of FSGS (Fig. 61.7).

CLINICAL MANIFESTATIONS

Presentation with Vesicoureteral Reflux

Patients with primary VUR may present in a variety of ways (Fig. 61.8). The three most common presentations are after a diagnosis of UTI, during follow-up for antenatal hydronephrosis, and on screening of a sibling of a patient with VUR.

Figure 61.4 Pathogenesis of VUR. Competent (left) and incompetent (right) vesicoureteral junctions and ureteral orifices.

Figure 61.5 Types of renal damage associated with VUR.

Types of Renal Damage Associated with VUR		
	Congenital	Acquired
Time of occurrence	Often prenatal	Postnatally, sometimes in adulthood
Previous urinary infection	Not usually	Usually
Gender	Usually boys	Usually girls (particularly after infancy)
Grade of VUR	Usually grades IV and V	Grades IV and V less common
Renal scarring	Often present	Present in minority of cases*
Associated bladder dysfunction	Hypercontractile bladder common	Less commonly high capacity bladder with incomplete voiding
*depends on unilateral versus bilateral involvement, and the severity of renal involvement

Clinical Presentations of VUR

Complicated urinary infection – usually acute pyelonephritis in infants and children

Asymptomatic

- Detected by fetal ultrasound
- Detected in the workup of members of an affected family
- Detected in pregnant women with UTI
- Detected during workup of kidney stones in children
- Detected during assessment of other urologic congenital abnormalities

Figure 61.8 Clinical presentations of VUR.

Reflux Identified After a Urinary Tract Infection

VUR is most commonly found after UTI, particularly in a young child. The prevalence of VUR is higher in younger subjects and decreases with age (Fig. 61.9). In neonates and toddlers, UTI may be manifested as failure to thrive as opposed to typical symptoms of dysuria and frequency. VUR is more common in subjects with complicated or upper tract UTI. Because VUR may potentiate the effect of UTI in children, current recommendations for evaluation of UTI include ultrasound and VCU after resolution of the first UTI in both boys and girls (Fig. 61.10). If

Prevalence of VUR in Patients with Urinary Tract Infection, According to Age

Age	Percentage with VUR
2–3 days	57
3–6 days	51
2–6 months	60
7–12 months	35
1–4 years	50
5–9 years	35
10–14 years	14
14 years	10
Adult	5

Figure 61.9 Prevalence of VUR in patients with urinary tract infection, according to age. (From reference 14.)

Algorithm for Evaluation of Young Children with Diagnosed UTI

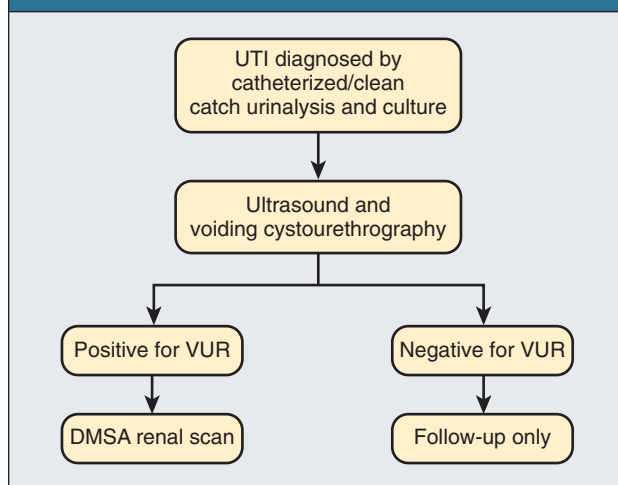

Figure 61.10 Current recommended algorithm for evaluation of young children with diagnosed UTI.

VUR is diagnosed, further testing involves a DMSA scan to determine whether renal scarring is present.

Most children diagnosed with VUR after a UTI are younger than 7 years. UTI in these subjects may be associated with modifiable host factors, such as voiding dysfunction and constipation. For example, toilet-trained children with VUR identified after a UTI, have a 43% incidence of dysfunctional voiding.¹⁵

Reflux Identified Secondary to Antenatal Hydronephrosis

Diagnosis of VUR may be suspected *in utero* with unilateral or bilateral hydronephrosis and confirmed at birth with VCU. There is a higher incidence of male infants diagnosed with VUR after identification of antenatal hydronephrosis.¹⁶ Spontaneous resolution of the VUR occurs more commonly in boys with lower grades and unilateral reflux; infection rates are also lower

in this cohort.¹⁷ Female infants are more likely to have lower grades of VUR and are also less likely to develop renal damage compared with newborn boys. Reflux in newborn boys may be due to elevated bladder pressures secondary to dyssynergia of the urethral sphincter, which improves with time with secondary resolution of even higher grades of VUR.^{18,19}

Sibling VUR

Approximately one third of siblings of an index patient with VUR also have VUR.¹⁸ There is a slightly higher incidence of VUR in female siblings of female index patients; 75% of children with VUR identified by sibling screening are asymptomatic. The incidence of renal damage is also lower in the siblings diagnosed with reflux compared with the index patient with VUR.²⁰ For example, UTI with progression of scar was noted in only 5% of siblings with VUR observed for 3 to 7 years, and most of those with grades I and II VUR had resolution.²¹ The more “benign” course of sibling reflux compared with reflux identified after a UTI has led many to suggest limitation of those being screened. At this time, most suggest screening of younger siblings (<5 years) of index children with VUR and reserve screening of older siblings for those who present with a UTI or other symptoms.

Reflux Nephropathy

VUR with or without UTI may cause renal scarring, which is known as reflux nephropathy.²² Young children are particularly at risk. Renal scarring is common with febrile UTI in children, and in those younger than 5 years, as many as 75% develop acute pyelonephritis and renal scarring. Renal cortical defects (by DMSA scanning) are present in 45% of children with febrile UTI and VUR compared with 24% with UTI without VUR.²³ In a large prospective study of a population-based cohort of 1221 children aged 0 to 15 years with symptomatic UTI, primary scarring during initial evaluation was even higher, occurring in 86% of the boys and 30% of the girls. Girls had significantly more recurrences of febrile UTIs and acquired renal scarring than boys.²⁴

The clinical manifestations of reflux nephropathy are varied and may include complicated UTI, hypertension, proteinuria, and various manifestations of CKD (Fig. 61.11).

Hypertension

Hypertension occurs in 10% to 30% of children and young adults with reflux nephropathy,^{24,25} and according to one study,

hypertension may take 8 years to develop.¹² The exact cause of hypertension due to renal scarring is not known, but it is believed to be due to impaired sodium excretion resulting from the renal injury. Hypertension is relatively uncommon in children with VUR, with an estimated probability of 2%, 6%, and 15% at 10, 15, and 21 years of age, respectively. However, hypertension increases in proportion to the degree of renal injury.²⁶ Renal scarring (noted by DMSA scans) was reported in 20% of newly diagnosed hypertension in children and adolescents.

Proteinuria

Patients may also present with microalbuminuria, persistent proteinuria, or rarely nephrotic-range proteinuria. The presence of proteinuria may suggest a histologic diagnosis of secondary FSGS, which can be confirmed by renal biopsy if kidney size is normal and diagnosis is uncertain (see Fig. 61.7).²⁷ Proteinuria is usually modest (0.5 to 4 g/day) and is commonly associated with hypertension and renal dysfunction. CKD progression often occurs gradually over 5 to 10 years.

End-Stage Renal Disease

According to the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) annual report of 2006, 8% of the 6405 children with ESRD had reflux nephropathy, which makes it the fourth most common cause of ESRD after obstructive uropathy, renal aplasia or hypoplasia or dysplasia, and FSGS.²⁸ Reflux nephropathy may also account for as much as 10% of ESRD in young to middle-aged adults.

Presentation of VUR in the Mother During Pregnancy

VUR may also first be manifested in the mother during pregnancy, when it can be associated with asymptomatic bacteriuria or symptomatic UTI, hypertension, preeclampsia, low-birth-weight babies, or miscarriage. VUR is present in approximately 5% of women with UTI in pregnancy and 4% to 5% of women with preeclampsia. VUR can be distinguished from the normal ureteral dilation that occurs in pregnancy, which preferentially affects the midportion of the ureter, and lack of involvement of the renal parenchyma.

Other Presentations

An increased risk of renal calculi has also been reported in children with VUR. Recurrent infections with urease-splitting organisms can lead to staghorn calculi. VUR or reflux nephropathy may also be discovered in adults after recurrent lower or upper UTI; indeed, about 5% of sexually active women with UTI have VUR.

DIAGNOSIS OF VESICoureTERAL REFLUX AND REFLUX NEPHROPATHY

An algorithm for diagnosis of VUR after the discovery of UTI is shown in Figure 61.10, and an example of the various tests in a child with UTI and VUR is shown in Figure 61.12. A similar approach should be performed in children after treatment of their first UTI.

Renal Ultrasound

Ultrasound is the initial modality for the evaluation of postnatal hydronephrosis and UTI in children. Ultrasound is also used as a screening tool in siblings of children with VUR to determine

Clinical Presentations of Reflux Nephropathy
Complicated urinary infection—usually acute pyelonephritis in infants and children
Hypertension: may be accelerated
During pregnancy: urinary infection, hypertension, preeclampsia
Proteinuria
Chronic renal impairment
Urinary calculi
Asymptomatic
Detected in the workup of members of an affected family
Detected by fetal ultrasound
Detected during assessment of other urologic congenital abnormalities

Figure 61.11
Clinical presentations of reflux nephropathy.

Figure 61.12 Investigation of reflux nephropathy. Investigation of a 3-year-old child with UTI. **A**, Intravenous urogram showing calyceal diverticulum in the upper pole of the right kidney and renal scarring in the upper pole and, probably, the lower pole of the left kidney. **B**, DMSA scintigraphy (posterior view) demonstrating upper and lower pole scarring (arrows) in the left kidney and scarring of the right upper kidney in association with the calyceal diverticulum (arrowhead). **C**, Voiding cystourethrogram showing grade IV VUR on the left.

whether high-grade reflux is present. Whereas ultrasound can diagnose high-grade VUR, it has less sensitivity for diagnosis of acute pyelonephritis. In patients with acute pyelonephritis, abnormalities compatible with the diagnosis were reported in 20% to 69% by ultrasound compared with 40% to 92% by DMSA scintigraphy.²⁹ Nonetheless, ultrasound may be useful in detection of renal abscess and abnormalities of the perinephric space. Renal ultrasound is not a sensitive method for diagnosis of renal scars.

Voiding Cystourethrography

VCU is the primary diagnostic modality for identification of VUR. It requires catheterization, which can lead to significant distress among both children and parents. The grading of VUR is based on radiographic appearance by VCU (see Fig. 61.1). In children with UTI, VCU should be performed as soon as the child has completed the course of antibiotic therapy. Evaluation with VCU has been suggested after the first febrile infection in children younger than 5 years.

The results of VCU can be affected by size, type, and position of the catheter; rate of bladder filling; height of the column of contrast media; state of hydration of the patient; and volume, temperature, and concentration of the contrast medium.

Nuclear cystography has been used to reduce the radiation exposure for children during follow-up of VUR. Nuclear cystography, although it is more sensitive, does not permit specific grading of VUR or reveal anatomic defects, such as ureterocele and diverticulum. Nevertheless, it is useful in determining resolution of reflux during follow-up or after surgical correction.

DMSA Renal Scan

DMSA scintigraphy is currently the accepted gold standard for diagnosis of acute pyelonephritis and renal scarring.

Single-photon emission computed tomography (SPECT) DMSA scintigraphy is superior to planar imaging for detection of renal cortical damage.^{30,31} The sensitivity of DMSA scintigraphy in experimentally induced acute pyelonephritis in a pig model was reported to be 92% compared with histologic findings.³² By use of standardized criteria for its interpretation, high levels of intraobserver and interobserver agreement were reported.³³

An abnormal DMSA scan during a febrile UTI allows the identification of children at risk for development of renal scars. For acute pyelonephritis, DMSA scintigraphy can be performed within 2 to 4 weeks after the onset of UTI symptoms. For renal scarring, DMSA scintigraphy should ideally be performed 6 months after acute infection to allow acute reversible lesions to resolve.³⁴

Dysplasia secondary to congenital reflux will appear similar to renal scarring after postnatal infections. In the context of a child presenting with VUR, obtaining a baseline DMSA renal scan allows identification of renal dysplasia and scarring, which can then be observed over time.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has recently been used for the diagnosis of renal scars because it discriminates swelling from scarring, both of which would be interpreted by DMSA scintigraphy as renal scarring. MRI may also diagnose other coexisting conditions, such as nephrolithiasis,^{35,36} which is not diagnosed by DMSA scintigraphy. Newer imaging methods that show promise in diagnosis of renal scarring include dynamic contrast-enhanced MRI and MRI using a gadolinium-enhanced short-tau inversion-recovery (STIR) sequence. However, routine use of MRI is less practical because of limited availability, need for prolonged sedation, and high cost. Gadolinium is also contraindicated in the presence of significant renal impairment (glomerular filtration rate <30 ml/min per 1.73 m²).

Proteinuria as a Marker for Reflux Nephropathy

Proteinuria predicts CKD progression due to reflux nephropathy.³⁷ Persistent microalbuminuria is helpful in diagnosis of glomerular damage at a very early stage.³⁸ Microalbuminuria increases with increasing severity of VUR and renal scarring.³⁹ In children with bilateral VUR with renal scarring and normal creatinine clearance, microalbuminuria was detected in 54% of the cases.⁴⁰ Microalbuminuria screening offers the possibility of early therapeutic intervention aimed at retarding CKD progress. Proteinuria, when it is severe, is usually associated with FSGS.

NATURAL HISTORY OF VESICoureTERAL REFLUX AND REFLUX NEPHROPATHY

Primary VUR, especially grades I to III, generally improves with time, and this is attributed to the lengthening of the submucosal segment of the ureter. Spontaneous resolution of VUR is more common with non-white race, lower grades of reflux, absence of renal damage, and lack of voiding dysfunction. Resolution of VUR occurs more slowly in children with bilateral VUR in most but not all studies. In one study of children younger than 5 years with grades I to III VUR, the resolution rate of left unilateral VUR was better than for right VUR.⁴¹ In another study, the mean time until spontaneous resolution in black children was 15 months versus 21 months in white children.⁴² Increasing age at presentation and bilateral VUR decrease the probability of resolution, and bilateral grade IV or grade V VUR has a particularly low chance of spontaneous resolution.⁴³

The natural history of VUR in adults has been reported in few studies. In one study of adults (mean age of 24 years) with gross VUR diagnosed in infancy, proteinuria and CKD were present in 3 of the 13 patients with unilateral reflux nephropathy and 2 of the 4 patients with bilateral reflux nephropathy.⁴⁴ In another study of 127 adults (mean age of 41 years) with VUR diagnosed during childhood, 35% had unilateral renal scarring, 24% had bilateral renal scarring, 24% had albuminuria, and 11% had hypertension. Of the patients with bilateral renal scars, 83% had abnormal glomerular filtration rates.⁴⁵ An increased frequency of UTI and abnormal voiding patterns has also been noted in adults with VUR. UTIs may also be increased in frequency in adults who have had surgical management of VUR.

TREATMENT

For many decades, the management of VUR has been driven by the belief that VUR predisposes to recurrent UTI and renal parenchymal damage. Various treatment strategies have been used with the ultimate objective of preventing renal injury. The two main treatment modalities that have been practiced are long-term antimicrobial prophylaxis and surgical correction. Surgical correction of VUR was common until antimicrobial prophylaxis for childhood UTI was introduced in 1975.⁴⁶ Many subsequent studies have reported no significant differences in outcome with medical management of VUR versus surgical treatment. For example, in the International Reflux Study in Children, which involved 306 patients, no significant difference in outcome was found between medical and surgical management in terms of the development of new renal lesions or the progression of established renal scars.⁴⁷ In the International Reflux Study Group in Europe, 287 children with severe VUR were randomly allocated to medical or surgical groups. Follow-up with DMSA renal scans for a period of 5 years again revealed no difference in outcome.⁹

The 1997 American Urological Association guidelines reviewed seven treatment modalities used to manage VUR in children: intermittent antibiotic therapy; bladder training; continuous antibiotic prophylaxis; antibiotic prophylaxis and bladder training; antibiotic prophylaxis, anticholinergics, and bladder training; open surgical repair; and endoscopic repair. The key outcome measures were resolution of VUR, risk of pyelonephritis and scarring, and complications of medical versus surgical management. The study panel's recommendations are shown in [Figure 61.13](#). Antibiotic prophylaxis is recommended for all grades of VUR in children younger than 1 year because of a very high rate of spontaneous resolution. For children 1 to 5 years old, the study panel recommended antibiotic prophylaxis for all grades of VUR, with surgical options in grades III to V if VUR is bilateral or renal scarring is present. For children older than 6 years, the study panel recommended antibiotic prophylaxis for grades I and II (unilateral or bilateral) and unilateral grades III and IV, with surgical options if renal scarring is present, and surgical repair for bilateral grades III and IV and unilateral or bilateral grade V with or without scarring as the VUR has the least possibility of spontaneous resolution.⁴⁸

Medical Management

Medical management involves long-term antimicrobial prophylaxis, appropriate management of voiding dysfunction and

constipation, if present, and follow-up renal imaging to assess the resolution of VUR and the potential development of renal injury.

The antimicrobial agents most appropriate for prophylaxis include trimethoprim-sulfamethoxazole (TMP-SMZ), trimethoprim alone, nitrofurantoin, and cephalexin. Follow-up of patients with VUR and UTI requires rapid evaluation (within 72 hours of the onset of fever) to allow early detection and prompt treatment of UTI. The timing of follow-up VCU is not well defined, although most practitioners do it yearly.

The treatment of voiding dysfunction or dysfunctional elimination syndrome may include the use of laxatives and timed frequent voiding every 2 to 3 hours. Pelvic floor exercises, behavioral modification, or anticholinergic medication may be required. A combined conservative medical and computer game-assisted pelvic floor muscle retraining decreased the incidence of breakthrough UTI and facilitated VUR resolution in children with voiding dysfunction and VUR. Treatment of constipation by dietary measures, behavioral therapy, and laxatives helps reduce UTI recurrence and the resolution of enuresis and uninhibited bladder contractions.

Antibiotic Prophylaxis Versus Surveillance Only

Some studies challenge the benefit of long-term antimicrobial prophylaxis in the prevention of renal injury in patients with VUR. A randomized study involved 236 children aged 3 months to 18 years with acute pyelonephritis; 113 children had grades I to III VUR (age group 3 months to 12 years) and 115 patients none (age group 3 months to 17 years). Patients were randomly assigned to prophylactic antibiotic (TMP-SMZ) or no prophylaxis. At the end of 1 year, no difference was noted in the incidence of UTI, pyelonephritis, or renal scarring by DMSA scans between the two groups, suggesting that there is no role for prophylactic antibiotics in preventing the recurrence of infection and the development of renal scars in such children.⁴⁹ In another study, 225 children aged 1 month to 3 years with grades I to III

VUR were randomized to daily antibiotic prophylaxis (TMP-SMZ) or no prophylaxis. After a follow-up period of 18 months, there was no significant difference in the occurrence of UTI. Antimicrobial prophylaxis did, however, reduce UTIs in boys ($P = .017$), particularly in those with grade III VUR.⁵⁰ In a third study, 100 babies 8 to 9 months old with grades II to IV VUR diagnosed after an upper tract UTI were randomized to TMP-SMZ prophylaxis for 2 years, then observed for another 2 years. There was no difference in recurrence of acute pyelonephritis during the 4 years of study. There was no difference in renal scarring at 2 years, and no patients were noted to have new renal scars after 4 years.¹¹ A fourth study of 338 children (aged 2 months to <7 years) with first febrile UTI included 128 children with grades I to III VUR. There was no effect of antimicrobial prophylaxis on the 12-month recurrence rate of febrile UTI in those with VUR.

These trials, although important, are not conclusive. Various study design limitations included small study size and short follow-up, lack of blinding, no use of placebo, urine collection by sterile bags in non-toilet-trained children, and exclusion of patients with high-grade VUR (who are normally associated with the highest risk of renal injury) as well as the issue of interobserver variability in the interpretation of DMSA renal scans.

Hypertension and Proteinuria

Appropriate management of hypertension and proteinuria includes the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) as in other renal diseases (see Chapter 76). ACE inhibitors reduce proteinuria in subjects with reflux nephropathy and also can reverse microalbuminuria. Combination of ACE inhibitor and ARB may provide additional lowering of proteinuria.⁵¹ However, it is not known whether this antiproteinuric effect slows the progression of the renal disease. Historically, some patients also occasionally had their scarred kidney removed to help control hypertension, provided the contralateral kidney was healthy. However, this is

Surgical Techniques for Management VUR			
Technique	Success Rates	Pros	Cons
Open reimplantation	95%	High success rates Limited requirement for follow-up VCU Reduction in hospital stays	Surgical incision Hospitalization required Catheters needed during postoperative management Pain control
Endoscopic injection Dextranomer/hyaluronidase (Deflux)	70%–80%	Reasonable success rates Outpatient management Minimal pain	Expensive Lower success rates Need for repeated procedures Need for follow-up VCU
Laparoscopic reimplantation	70%–90%	Reasonable success rates Small incisions Less discomfort	Lower success rates Requires hospitalization Need for follow-up VCU Long procedure Expensive equipment Significant surgical learning curve

Figure 61.14 Surgical techniques for VUR. VCU, voiding cystourethrography.

exceptionally rare these days because of the availability of many potent antihypertensive agents.

Surgical Management

Surgical management of VUR is now a second-line management strategy and is reserved for patients whose medical management with antimicrobial prophylaxis and follow-up has failed. Current indications for surgical management of VUR are recurrent infections despite compliance with a prophylactic antibiotic regimen, worsening of renal scars after a UTI, and repeated failure to comply with a prophylactic regimen. The recent introduction of minimally invasive modalities for the management of VUR has made some clinicians consider surgical correction a potential first-line therapy. Immediate correction could potentially offset the need for antibiotic prophylaxis in children. Although most surgical techniques have high success rates, most studies indicate that surgical correction of VUR does not prevent UTI or eventual renal scarring.⁵² A review of surgical techniques is presented in Figure 61.14.

Chronic Interstitial Nephritis

Masaomi Nangaku, Toshiro Fujita

DEFINITION

Chronic interstitial nephritis is a histologic entity characterized by progressive scarring of the tubulointerstitium, with tubular atrophy, macrophage and lymphocytic infiltration, and interstitial fibrosis. Because the degree of tubular damage accompanying interstitial nephritis is variable, the term *tubulointerstitial nephritis* is used interchangeably with interstitial nephritis. *Tubulitis* refers to infiltration of the tubular epithelium by leukocytes, usually lymphocytes.

There are many primary as well as secondary causes of chronic interstitial nephritis (Fig. 62.1). Tubulointerstitial injury is clinically important because it is a better predictor than the degree of glomerular injury of present and future renal function. Although any glomerular disease can injure the tubulointerstitium secondarily through mechanisms involving the direct effects of proteinuria and ischemia, we restrict our discussion to primary chronic interstitial nephritis.

PATHOGENESIS

The tubulointerstitium can be injured by toxins (e.g., heavy metals), drugs (e.g., analgesics), crystals (e.g., calcium phosphate, uric acid), infections, obstruction, immunologic mechanisms, and ischemia. Regardless of the initiating mechanism, however, the tubulointerstitial response shows little variation. Tubular injury results in the release of chemotactic substances and the expression of leukocyte adhesion molecules that attract inflammatory cells into the interstitium. Tubular cells express human leukocyte antigens, serve as antigen-presenting cells, and secrete complement components and vasoactive mediators, all of which may further stimulate or attract macrophages and T cells. Growth factors released by tubular cells and macrophages, such as platelet-derived growth factor and transforming growth factor β , may stimulate fibroblast proliferation and activation, leading to matrix accumulation.¹ The source of fibroblasts in renal interstitial fibrosis remains controversial but may include an intrinsic fibroblast population, migration of circulating fibrocytes from perivascular areas, and transdifferentiation of tubular cells, pericytes, and endothelial cells into fibroblasts.² Over time, a loss of peritubular capillaries and decreased oxygen diffusion due to expansion of the interstitium render the kidney hypoxic, and progressive apoptosis leads to local hypocellularity and fibrosis.³ Renal function becomes severely decreased, and renal replacement therapies are required.

EPIDEMIOLOGY

Whereas chronic interstitial nephritis occurs with progressive renal disease of all etiologies, primary chronic interstitial nephri-

tis is not a common cause of end-stage renal disease (ESRD); reports range from 42% in Scotland to 3% to 4% in China and the United States.⁴⁻⁶ This variability in incidence may relate to differences in how diagnoses are made, etiologies and toxin or drug exposure, and treatment modalities.

PATHOLOGY

The pathologic features of chronic interstitial nephritis are nonspecific. They include tubular cell atrophy or dilation; interstitial fibrosis that is composed of interstitial (types I and II) collagens; and mononuclear cell infiltration with macrophages, T cells, and occasionally other cell types (neutrophils, eosinophils, and plasma cells). Tubular lumina vary in diameter but may show marked dilation, with homogeneous casts producing a thyroid-like appearance, hence the term *thyroidization*.

Whereas a noncaseating granulomatous pattern is observed in sarcoidosis, interstitial granulomatous reactions also occur in response to infection of the kidney by mycobacteria (Fig. 62.2), fungi, or bacteria; drugs (rifampin, sulfonamides, and narcotics); and oxalate or urate crystal deposition. Interstitial granulomatous reactions also have been noted in renal malacoplakia, Wegener's granulomatosis, and heroin abuse and after jejunoileal bypass surgery.

CLINICAL MANIFESTATIONS

The impaired renal function is often insidious, and the early manifestations of the disease are those of tubular dysfunction, which may go undetected (Fig. 62.3).⁷ Diagnosis is often made incidentally on routine laboratory screening or during evaluation of hypertension, in association with reduced glomerular filtration rate (GFR). Proteinuria is commonly less than 1 g/day. The urinalysis may show only occasional white blood cells and, rarely, white blood cell casts. Hematuria is uncommon. Anemia may occur relatively early because of loss of erythropoietin-producing interstitial cells.

The tubular dysfunction is often generalized, but some conditions may present with proximal tubular defects including aminoaciduria, phosphaturia, proximal renal tubular acidosis (RTA), or, rarely, a complete Fanconi syndrome. Distal tubular defects can be associated with type 4 RTA (see Chapter 12). Concentrating defects (increased urinary frequency and nocturia) can be a sign of medullary dysfunction and may be severe enough to result in nephrogenic diabetes insipidus. Some subjects will also have an inability to conserve salt on a low-salt diet with subsequent salt-wasting syndrome. Others, particularly with microvascular disease, may have a relative inability to excrete salt with resultant salt-sensitive hypertension.⁸

Major Etiologies of Chronic Interstitial Nephritis	
Diseases in which the Kidneys Are Macroscopically Normal	Diseases in which the Kidneys Are Macroscopically Abnormal
Drugs and toxins (e.g., aristolochic acid, lithium, cyclosporine, tacrolimus, indinavir, cisplatin)	Analgesic nephropathy
Metabolic (hyperuricemia, hypokalemia, hypercalcemia, hyperoxaluria, cystinosis)	Chronic obstruction (see Chapters 58 and 61)
Heavy metals (lead, cadmium, arsenic, mercury, gold, uranium)	Hereditary (nephronophthisis, medullary cystic kidney disease, familial juvenile hyperuricemic nephropathy, autosomal dominant polycystic kidney disease, autosomal recessive polycystic kidney disease)
Radiation	Infection (chronic pyelonephritis, malacoplakia, xanthogranulomatous pyelonephritis; see Chapter 51)
Balkan nephropathy	
Immune-mediated (systemic lupus erythematosus, Sjögren's syndrome, sarcoidosis, Wegener's granulomatosis, other vasculitides)	
Vascular diseases (atherosclerotic kidney disease) (see Chapter 64)	
Transplantation (chronic transplant rejection)	
Hematologic disturbances (multiple myeloma, light-chain deposition disease, lymphoma, sickle cell disease, paroxysmal nocturnal hemoglobinuria) (see Chapters 26, 49, and 63)	
Progressive glomerular disease of all etiologies (e.g., glomerulonephritides, diabetes, hypertension)	
Idiopathic	

Figure 62.1 Major etiologies of chronic interstitial nephritis. Note that kidneys of any clinical entity can be shrunken at end-stage. Some diseases categorized as macroscopically normal can show macroscopically abnormal kidneys. For example, kidneys of sickle cell nephropathy are macroscopically normal unless there is papillary necrosis.

Figure 62.2 Renal tuberculosis. Noncaseating granulomas with epithelioid cells in miliary tuberculosis (arrows). Although the typical pathologic change is granuloma with caseous necrosis with Langerhans-type giant cells, these nontypical granulomas can be observed in tuberculosis and should be differentiated from sarcoidosis. (Hematoxylin and eosin stain.) (Courtesy Dr. Noriko Uesugi, Ibaraki, Japan.)

Clues to tubulointerstitial nephritis by history and physical examination are shown in Figure 62.4.⁹

TREATMENT

Treatment includes identification and elimination of any exogenous agents (drugs, heavy metals), metabolic causes (hypercalcemia), or conditions (obstruction, infection) potentially causing the chronic interstitial lesion. Specific treatments may be required for a condition, such as corticosteroids for sarcoidosis. General measures include control of blood pressure. Most clinicians favor

Functional Manifestations of Chronic Interstitial Nephritis
Deterioration of glomerular filtration rate with insidious onset
Tubular proteinuria mainly composed of low-molecular-weight protein (generally <1 g/day)
Inactive urinary sediment
Renal anemia at a relatively early stage
Proximal tubular dysfunction (aminoaciduria, phosphaturia, proximal renal tubular acidosis, Fanconi syndrome)
Distal tubular dysfunction (type IV renal tubular acidosis)
Medullary dysfunction (concentrating defects)
Salt-wasting syndrome
Salt-sensitive hypertension

Figure 62.3 Functional manifestations of chronic interstitial nephritis.

the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs), which reduce glomerular and systemic pressures, decrease proteinuria, and increase renal blood flow. Specific therapies for each clinical entity are discussed later.

DRUG-INDUCED CHRONIC INTERSTITIAL NEPHRITIS

Several drugs and herbs can cause chronic interstitial nephritis. Cyclosporine- and tacrolimus-induced nephropathy is discussed in Chapter 100; aristolochic acid as a cause of aristolochic acid-associated nephropathy (Chinese herbs nephropathy) is discussed in Chapter 74.

Clues to Tubulointerstitial Nephritis by History and Physical Examination		
Element of Encounter	Symptom, Sign, or Historical Clue	Potential Diagnosis
Occupational history	Exposure to heavy metals (e.g., batteries, alloys)	Lead or cadmium nephropathy
Alcohol	History of moonshine ingestion	Lead nephropathy
Social history	Country of origin	Balkan nephropathy
Past history	Systemic lupus erythematosus Sjögren's syndrome, Sarcoidosis Inflammatory bowel disease Autoimmune pancreatitis Chronic pain syndrome Gouty attack	Disease-associated chronic interstitial nephritis Analgesic nephropathy Lead nephropathy
Medication	Prescribed Over-the-counter (NSAIDs) Herbal Indinavir	Drug-induced chronic interstitial nephritis Analgesic nephropathy Aristolochic acid-associated nephropathy Crystal nephropathy
Physical examination	Dry eyes	Sjögren's syndrome
Laboratory examination	Hyperuricemia Hypokalemia Hypercalcemia High serum IgG4 levels	Chronic urate nephropathy Hypokalemic nephropathy Hypercalcemic nephropathy IgG4-related sclerosing disease
Radiologic examination	Decreased volume, bumpy contours, and papillary calcification on CT Microcysts on MRI or echography Nephrocalcinosis on CT	Analgesic nephropathy Lithium nephropathy Hypercalcemic nephropathy

Figure 62.4 Clues to tubulointerstitial nephritis by history and physical examination. CT, computed tomography; MRI, magnetic resonance imaging; NSAIDs, nonsteroidal anti-inflammatory drugs. (Modified from reference 9.)

Lithium Nephropathy

Definition and Epidemiology

Lithium is commonly used in the treatment of bipolar disorder. Complications of lithium treatment include nephrogenic diabetes insipidus, acute lithium intoxication, and chronic lithium nephrotoxicity. A meta-analysis of the data of 14 studies involving 1172 patients receiving chronic lithium therapy showed that the prevalence of reduced GFR was 15%.¹⁰

Pathogenesis

Diabetes insipidus results from accumulation of lithium in the collecting tubular cells after entry into these cells through sodium channels in the luminal membrane. Lithium blocks vasopressin-induced reabsorption by inhibiting adenylate cyclase activity, and hence cyclic adenosine monophosphate production, and also by decreasing the apical membrane expression of aquaporin 2, the collecting tubule water channel. Chronic lithium-induced interstitial nephritis may also occur, possibly due to inositol depletion and inhibition of cell proliferation.

Pathology

Biopsies show focal chronic interstitial nephritis with interstitial fibrosis, tubular atrophy, and glomerular sclerosis. Whereas similar histologic changes have been reported in psychiatric

subjects without a history of lithium therapy, subjects with lithium exposure often show microcystic changes in the distal tubule; interstitial inflammation and vascular changes are relatively minimal. The degree of interstitial fibrosis is related to the duration of administration and cumulative dose.

Clinical Manifestations

Lithium-Associated Diabetes Insipidus The most common presentation of lithium-induced nephrotoxicity is nephrogenic diabetes insipidus, characterized by resistance to vasopressin, polyuria, and polydipsia. Impaired renal concentrating ability is found in about 50% of patients, and polyuria due to nephrogenic diabetes insipidus occurs in about 20% of patients chronically treated with lithium.

Lithium is also rarely a cause of hypercalcemia, which could potentially exaggerate the tubular concentrating defect and contribute to the development of chronic interstitial nephritis in lithium-treated patients. Nephrogenic diabetes insipidus in lithium treatment may be associated with distal RTA, although this partial functional defect is virtually never of clinical importance.

Chronic Lithium Nephropathy Nephrogenic diabetes insipidus induced by lithium may persist despite the cessation of treatment, indicating irreversible renal damage.

In one study, the mean serum creatinine concentration of patients with biopsy-proven chronic lithium nephrotoxicity was 2.8 mg/dl (247 μ mol/l) at the time of biopsy, and 42% of patients had proteinuria greater than 1 g/day.¹¹ After renal biopsy, all but one patient discontinued treatment with lithium, but seven patients nevertheless progressed to ESRD. A study of 74 lithium-treated patients in France showed that lithium-induced nephropathy developed slowly during several decades, with an average latency between the start of therapy and ESRD of 20 years.¹²

Magnetic resonance imaging or ultrasound may help in the detection of the microcysts in the kidney.¹³

Treatment

After other potential causes of polyuria and polydipsia have been excluded, particularly psychogenic polydipsia, the first step to consider is a reduction in lithium dosage. The potassium-sparing diuretic amiloride improves the polyuria and also blocks lithium uptake through sodium channels in the collecting duct. Thiazide diuretics should be avoided as they increase the risk for acute lithium intoxication because of the resultant volume contraction and an increase in sodium and lithium reabsorption in the proximal tubule.

Patients receiving long-term lithium treatment should have renal function (serum creatinine and estimated GFR) and 24-hour urine volume measured yearly. Lithium has a narrow therapeutic index, so levels should be monitored and maintained between 0.6 and 1.25 mmol/l. The severity of chronic lithium intoxication correlates directly with the serum lithium concentration and may be categorized as mild (1.5 to 2.0 mmol/l), moderate (2.0 to 2.5 mmol/l), or severe (>2.5 mmol/l). Once-daily regimens are less toxic than multiple daily dose schedules, perhaps because of the possibility of renal tubular regeneration with a once-daily dosing schedule.¹⁴ Prevention of volume depletion is also important.

Because progressive renal injury with reduced GFR in patients without prior acute lithium intoxication is relatively unusual, raised serum creatinine concentration should initially be treated by a dose reduction. If there is persistently elevated serum creatinine, a renal biopsy should be considered, although the findings rarely mandate the complete cessation of lithium treatment. At all times, the risk for discontinuation in a patient with a severe unipolar or bipolar affective disorder needs to be balanced with the relatively low risk for progressive renal injury.

Analgesic Nephropathy

Definition and Epidemiology

Analgesic nephropathy resulted from the abuse of analgesics, commonly mixtures containing phenacetin, aspirin, and caffeine that were available as over-the-counter preparations in Europe and Australia. It is now rare; indeed, some doubt that new cases are still presenting, following restrictions in compound analgesic sales.¹⁵ Long-term use of aspirin alone is not associated with analgesic nephropathy, and although long-term nonsteroidal anti-inflammatory drug use has been associated with chronic interstitial nephritis in a small number of patients, a large-scale case-control study found no increased risk of ESRD in users of combined or single formulations of phenacetin-free analgesics.¹⁶ A large study in the United States also showed no association between use of current analgesic preparations and increased risk of renal dysfunction.¹⁷

Figure 62.5 Histologic changes in analgesic nephropathy. **A**, Interstitial nephritis in a patient with analgesic nephropathy associated with marked mononuclear cellular infiltrate including eosinophils (arrows). (Hematoxylin and eosin stain; original magnification $\times 600$.) **B**, Analgesic nephropathy with interstitial fibrosis and inflammatory cell infiltration. (Masson trichrome stain; original magnification $\times 400$.) (Courtesy Drs. Akira Shimizu and Hideki Takano, Nippon Medical School, Tokyo, Japan.)

Pathogenesis and Pathology

The primary injury in analgesic nephropathy is medullary ischemia due to toxic concentrations of phenacetin metabolites combined with relative medullary hypoxia, aggravated by inhibition of vasodilatory prostaglandin synthesis. The main pathologic consequence is papillary necrosis, with secondary tubular atrophy, interstitial fibrosis, and a mononuclear cellular infiltrate (Fig. 62.5).

Clinical Manifestations

Analgesic nephropathy was five to seven times more common in women than in men. Renal manifestations are nonspecific and consist of slowly progressive chronic renal failure with impaired urine concentrating ability, urinary acidification defects, and impaired sodium conservation. Urinalysis showed sterile pyuria and mild proteinuria. Patients with analgesic nephropathy are at increased risk for transitional cell carcinoma of the uroepithelium.

Diagnosis

Papillary necrosis is present histologically in almost all patients, but it can be detected radiologically only if part or all of the

Figure 62.6 Papillary calcifications in analgesic nephropathy. Non-contrast-enhanced CT scan of a patient with long-time analgesic abuse showed thinning of the renal parenchyma and typical papillary calcifications (arrows). (Courtesy Dr. Yoshifumi Ubara, Toranomon Hospital, Tokyo, Japan.)

papilla has sloughed. Papillary necrosis is not pathognomonic of analgesic nephropathy; it is also seen in diabetic nephropathy (particularly during an episode of acute pyelonephritis), sickle cell nephropathy, urinary tract obstruction, and renal tuberculosis. Non-contrast-enhanced computed tomography (CT) demonstrates a decrease in renal mass with either bumpy contours or papillary calcifications (Fig. 62.6).¹⁸

Treatment

Management consists of stopping or at least reducing the intake of analgesic medications. Because of the increased incidence of uroepithelial tumors, close follow-up is necessary. New hematuria requires early referral for urologic evaluation.

Analgesic nephropathy associated with over the counter medicines is also discussed in Chapter 74.

CHRONIC INTERSTITIAL NEPHRITIS DUE TO METABOLIC DISORDERS

Metabolic disorders causing interstitial nephritis are discussed here. Hyperoxaluria is described in Chapter 57 and cystinosis in Chapter 48.

Chronic Urate Nephropathy

Definition and Epidemiology

Historically, chronic interstitial nephritis associated with chronic hyperuricemia was called gouty nephropathy. Before drugs that lower uric acid levels became available, more than 50% of patients with gout had impaired renal function and nearly 100% had renal disease at autopsy. In the early 1980s, the concept of gouty nephropathy as a disease was challenged because the renal injury observed in subjects with gout was ascribed to coexistent hypertension, vascular disease, or aging-associated renal injury.¹⁹ However, epidemiologic studies suggest that an elevated serum uric acid level may carry an independent and dose-dependent risk for kidney disease.²⁰ These increases in risk remained significant even after adjustment for estimated GFR, proteinuria, age, and components of the metabolic syndrome. These studies

raise the interesting possibility that chronic hyperuricemia may be both a true risk factor for the development of chronic kidney disease (CKD) and a risk factor for progression of established CKD.

Pathogenesis

It has been suggested that chronic hyperuricemia and uricosuria result in intratubular sodium urate crystal deposition, with local obstruction, rupture into the interstitium, and subsequent granulomatous response and interstitial fibrosis. The determinants of uric acid solubility are its concentration and the pH of the tubular fluid, and the major sites of urate deposition are the renal medullae. If deposition occurs in an acid medium, as in the tubular fluid, birefringent uric acid crystals are formed; whereas in an alkaline medium, as in the interstitium, amorphous urate salts are deposited.

Crystalline deposits of urate may account for some degree of renal injury, but subjects with gouty nephropathy often have diffuse renal disease with arteriolosclerosis, focal and global glomerulosclerosis, and interstitial fibrosis. Although it is difficult to ascribe diffuse renal disease to the presence of focal crystalline deposits, experimental studies have suggested that hyperuricemia may induce chronic renal injury independent of crystal formation.²¹ The mechanism appears to be the development of preglomerular arteriolar disease that impairs the renal autoregulatory response and thereby causes glomerular hypertension.

Pathology

Renal functional abnormalities are observed in 30% to 50% of patients who have had gout for many years, and histologic changes are observed in more than 90%.²² On histologic examination, the lesion is characterized by tubulointerstitial fibrosis, often with arteriolosclerosis and glomerulosclerosis. Within the kidney, there are often precipitated uric acid crystals in the tubules and in the interstitium, particularly in the medulla (Fig. 62.7). On occasion, medullary renal tophi are found on gross anatomic dissection.

Clinical Manifestations

Patients present with hypertension with mildly impaired renal function, mild proteinuria, unremarkable urinary sediment, and minor tubular dysfunction (usually impairment of urine concentrating ability manifested as isosthenuria). Uric acid nephropathy should be particularly considered if there is a disproportionate elevation in serum uric acid in relation to the degree of renal impairment (Fig. 62.8).²³

Diagnosis

The most important differential diagnosis for gouty nephropathy is chronic lead nephropathy. Familial juvenile hyperuricemic nephropathy is a rare autosomal dominant disease that mimics chronic gouty nephropathy but that presents in adolescence or during early childhood (see Chapter 48).

Treatment

Whether lowering of uric acid is renoprotective remains controversial. One prospective, randomized, controlled trial demonstrated that allopurinol therapy is associated with preservation of renal function in mild to moderate CKD.²⁴ Withdrawal of allopurinol from patients with stable CKD resulted in worsening of hypertension and acceleration of kidney dysfunction.²⁵ More studies are required before treatment of hyperuricemia should be routinely offered.

Figure 62.7 Chronic urate nephropathy. **A**, Large collections of elongated or fragmented urate crystals are present in association with atrophic tubules. (Hematoxylin and eosin stain; original magnification $\times 400$.) **B**, The crystalline masses are refractile under polarized light. (Courtesy Drs. Akira Shimizu and Hideki Takano, Nippon Medical School, Tokyo, Japan.)

Expected Relationship of Serum Creatinine and Uric Acid Levels			
Serum Creatinine		Corresponding Serum Uric Acid Level	
mg/dl	$\mu\text{mol/l}$	mg/dl	$\mu\text{mol/l}$
<1.5	132	9	536
1.5–2.0	132–176	10	595
>2.0	176	12	714

Figure 62.8 Expected relationship of serum creatinine and uric acid levels. Serum uric acid disproportionately elevated above the expected values for serum creatinine suggests a diagnosis of chronic uric acid nephropathy. (Modified from reference 23.)

One reason for caution is the accumulation of the xanthine oxidase inhibitor allopurinol in renal failure. It is prudent to initiate allopurinol at a dose of 50 to 100 mg/day, increasing to 200 or 300 mg/day if it is tolerated. A small minority of patients (0.1%) develop a hypersensitivity syndrome that can be fatal, and

Figure 62.9 Hypokalemic nephropathy. Vacuolization of the renal tubules is observed in association with interstitial fibrosis in a patient with hypokalemic nephropathy. (Masson trichrome stain; original magnification $\times 400$.) (Courtesy Drs. Akira Shimizu and Hideki Takano, Nippon Medical School, Tokyo, Japan.)

this risk is increased with renal dysfunction. Experimentally, allopurinol can also be associated with nephrotoxicity in the setting of significant renal dysfunction by formation of allopurinol microcrystals. The newer xanthine oxidase inhibitor febuxostat does not require modification of dose in renal failure, nor is it associated with hypersensitivity or nephrotoxicity, but more studies are required before its use can be recommended.

Hypokalemic Nephropathy

Definition and Epidemiology

Hypokalemia, if persistent for prolonged periods, can induce renal cysts, chronic interstitial nephritis, and progressive loss of renal function, so-called hypokalemic nephropathy, which can be inherited or acquired.

Pathology

The characteristic finding is vacuolation of the renal tubules due to dilation of cisternae of the endoplasmic reticulum and basal folding, which is generally limited to the proximal tubule segments (Fig. 62.9). This abnormality generally requires at least one month to develop and is reversible with potassium supplementation. More prolonged hypokalemia can lead to more severe changes, predominantly in the renal medulla, including interstitial fibrosis, tubular atrophy, and cyst formation. There is experimental evidence that hypokalemic injury may be due to hypokalemia-induced renal vasoconstriction with ischemia. Local ammonia production stimulated by hypokalemia may also lead to intrarenal complement activation that may contribute to the renal injury. Furthermore, the associated intracellular acidosis can stimulate cell proliferation, which may account for the occasional development of cysts in hypokalemic subjects.

Clinical Manifestations

Impaired urine concentration, presenting with nocturia, polyuria, and polydipsia, may occur, particularly when plasma potassium concentration is consistently below 3.0 mmol/l for months or years. The average duration of hypokalemia reported in patients with chronic hypokalemic nephropathy is between 3.5

and 9 years. The renal defect is associated with decreased collecting tubule responsiveness to vasopressin, possibly due to decreased expression of aquaporin 2.

Diagnosis

Although degenerative changes in proximal tubular cells are a consistent but nonspecific finding in hypokalemic nephropathy, a particularly characteristic finding is vacuolar changes in the proximal tubules. Similar vacuolization of the convoluted tubules is observed in ethylene glycol poisoning.

Treatment

Hypokalemia can usually be treated with oral potassium supplements. Details about treatment of hypokalemia are described in Chapter 9. Coarse cytoplasmic vacuoles may persist for some time after normalization of serum potassium values.

Hypercalcemic Nephropathy

Definition and Epidemiology

Hypercalcemia can cause both a transient and reversible renal vasoconstriction with a decrement in renal function and a chronic interstitial nephritis secondary to tubular cell necrosis and intratubular obstruction. In addition, hypoparathyroidism (especially surgically induced after treatment of hyperparathyroidism) can also result in marked hypercalciuria and a similar syndrome in the absence of hypercalcemia.

Pathology

Focal degeneration and necrosis of the tubular epithelium, primarily in the medulla where calcium is concentrated, develop soon with persistent hypercalcemia. Although focal degenerative and necrotic lesions of the tubular epithelium can be observed in acute hypercalcemic patients, the most distinctive histologic feature of long-standing hypercalcemia is calcific deposits in the interstitium (nephrocalcinosis; Fig. 62.10). Deposition begins in the medullary tubules, followed by deposition in the cortical proximal and distal tubules and within the interstitial space, and secondarily leads to mononuclear cell infiltration and tubular necrosis.

Clinical Manifestations

Macroscopic nephrocalcinosis is often detected on radiography or ultrasound. A defect in urinary concentration is the most notable tubular dysfunction and is manifested as polyuria and polydipsia. The mechanism is incompletely understood, but the impairment relates both to a reduction in medullary solute content and to interference with the cellular response to vasopressin. Reversible impairment of renal function can result from either acute or chronic hypercalcemia by decreased renal blood flow and GFR. Irreversible renal failure is a rare consequence of long-standing hypercalcemia and is almost invariably associated with calcium crystal deposition in the interstitium of the kidney.

CHRONIC INTERSTITIAL NEPHRITIS DUE TO HEREDITARY DISEASES OF THE KIDNEY

Nephronophthisis (NPHP) and medullary cystic kidney disease (MCKD) (or the NPHP-MCKD complex) are hereditary diseases associated with renal cysts at the corticomedullary junction. These disorders are described in detail in Chapters 45 and 48.

Figure 62.10 Hypercalcemic nephropathy due to sarcoidosis. **A**, Marked tubular atrophy and interstitial fibrosis with mild lymphocytic infiltrate. **B**, Dense calcium deposits are seen in the thickened basement membrane of the atrophic tubules and in the fibrotic area of interstitium (serial section of **A**). **C**, Intraluminal calcium plaque in the atrophic tubules. CHRONIC INTERSTITIAL NEPHRITIS ASSOCIATED WITH HEAVY METAL EXPOSURE

Lead Nephropathy

Definition and Epidemiology

Acute lead intoxication is rare but may present with abdominal pain, encephalopathy, hemolytic anemia, peripheral neuropathy, and proximal tubular dysfunction (Fanconi syndrome). Because lead has a biologic half-life of several decades, both intermittent acute poisoning and low-level environmental exposure result in chronic cumulative lead poisoning. An epidemic of childhood lead poisoning in Queensland, Australia, established chronic lead nephropathy as a recognized clinical and pathologic entity.²⁶ The pathogenesis of the renal disease may be related to the accumulation of reabsorbed lead in the proximal tubule cells and effects of chronic lead exposure on the vasculature.

Epidemiologic studies have suggested that low-level exposure may be associated with CKD or hypertension in the general population.²⁷ Accelerated deterioration of renal function with low-level environmental lead exposure was confirmed in a prospective study of 121 patients with CKD.²⁸ Experimental studies showed that rats exposed to lead developed tubulointerstitial damage, peritubular capillary loss, and intrarenal arteriolar disease.²⁹

Pathology

The kidneys are reduced in size. The characteristic morphology is relatively acellular interstitial nephritis. The earliest histologic finding is proximal tubular injury, with intranuclear inclusion bodies composed of a lead-protein complex. Glomeruli are normal, and arteries and arterioles demonstrate medial thickening and luminal narrowing, probably related to hypertension. Immunofluorescence studies are noncontributory.

Clinical Manifestations

Chronic lead nephropathy is usually identified when a source of high exposure is known (occupational hazard or consumption of illicitly distilled spirits [moonshine]). Hyperuricemia is common because of impaired uric acid excretion. Urine sediment is benign, and urinary protein excretion is less than 2 g/day. Hypertension is almost always present, and in the absence of appropriate testing or a careful exposure history, lead nephropathy is often misdiagnosed as hypertensive kidney disease. Gouty arthritis ("saturnine gout") affects about half of patients. Patients with chronic lead intoxication may occasionally manifest other signs, including peripheral motor neuropathies, anemia with "basophilic" stippling, and perivascular cerebellar calcifications.

Diagnosis

Lead nephropathy is underdiagnosed because no simple diagnostic blood test is available. Lead nephropathy is easily confused with chronic urate nephropathy, in which urate deposits (tophi) may form in the renal interstitium. All patients with hyperuricemia and renal insufficiency should have a history of occupational lead exposure excluded. The blood lead concentration is an insensitive measure of cumulative body stores. A clinical diagnosis of lead nephropathy is based on a history of exposure, evidence of renal dysfunction, and a positive result of a calcium disodium edetate (CaNa₂ EDTA) lead chelation test.³⁰ The association with gout and CKD is strong enough to merit lead chelation screening in patients with CKD who have gout and risk of lead exposure. CaNa₂ EDTA is administered (two doses of 0.5 g

in 250 ml 5% dextrose given 12 hours apart), and urine is collected for 3 days because urinary excretion is slowed in the setting of renal failure. Normal urinary lead levels are less than 650 µg per 3 days. X-ray fluorescence, which provokes the emission of fluorescent photons from the target area, is an alternative method that detects increased bone lead levels, which are also a reflection of cumulative lead exposure.

Treatment

Treatment involves the infusions of CaNa₂ EDTA together with removal of the source of lead. The likelihood of a satisfactory response to CaNa₂ EDTA is influenced by the degree of interstitial fibrosis that has already occurred.

In industrial and occupational settings, such as in foundry workers and individuals working with lead-based paints and glazes, preventive measures to minimize exposure and low-level absorption are essential. The oral chelating agent succimer (Chemet) has proved highly successful in treating children. Chelation therapy may slow progressive CKD, even in patients with mild lead intoxication.³¹ However, the chelation therapy has not been widely used in adults. It is generally not indicated for adults with blood lead concentrations of less than 45 µg/dl because of the potential risk of adverse drug events and concerns about remobilized lead.

Other Heavy Metal–Induced Nephropathies

Cadmium is a metal with a wide variety of industrial uses, including the manufacture of glass, metal alloys, and electrical equipment. Cadmium is preferentially concentrated in the kidney, principally in the proximal tubule, in the form of a cadmium-metallothionein complex that has a biologic half-life of about 10 years. A major outbreak of cadmium toxicity occurred in Japan as a result of industrial contamination. The disease was called *itai-itai*, or "ouch-ouch," because of the significant bone pain as the major clinical manifestation. Other manifestations included proximal tubular dysfunction, renal stones caused by hypercalciuria, anemia, and rarely progressive chronic interstitial nephritis. The mechanism by which cadmium elicits chronic inflammation and fibrosis in the kidney is relatively unstudied. The diagnosis is suggested by a history of occupational exposure, increased urinary β₂-microglobulin, and increased urinary cadmium levels (>7 µg/g creatinine). Once manifested, renal injury tends to be progressive, even if exposure is discontinued. Chelation has not been effective in humans, and prevention is the only effective treatment.

Arsenic, used as a poison gas in the First World War, is present in insecticides, weed killers, wallpaper, and paints. Chronic arsenic toxicity most commonly is manifested as sensory and motor neuropathies, distal extremity hyperkeratosis, palmar desquamation, diarrhea and nausea, Aldrich-Mees lines (white bands on the nails), and anemia. In rare cases, it may cause renal disease, manifested by both proximal RTA and chronic interstitial fibrosis. Diagnosis is made by demonstration of an elevated urinary arsenic level.

Mercury is found in alloy plants, mirror plants, and some batteries, and mercury intoxication usually occurs as a result of accidental exposure to mercury vapor. Although mercury has been shown to induce membranous nephropathy in experimental animals, the nephrotic syndrome is so uncommon in humans exposed to mercury that its etiologic role has been doubted. Neither elemental mercury nor the mercurous salt (Hg₂Cl₂) produces sustained renal tubular injury, but mercury dichloride

(HgCl_2) may produce acute tubular necrosis and subsequent chronic interstitial nephritis. However, a report of endemic methyl mercury poisoning in Japan revealed a clinical picture dominated by neurologic sequelae; renal disease in these patients was surprisingly benign, consisting only of tubular proteinuria without changes in serum creatinine.

RADIATION NEPHRITIS

Definition and Epidemiology

Although radiation nephritis was relatively common decades ago, the incidence has decreased considerably because recognition of radiation-induced renal damage has altered protocols for the administration of therapeutic radiation. In general, direct exposure of the kidney to 20 to 30 Gy (1 Gy = 100 rad) during 5 weeks or less will produce radiation nephritis.

Pathology

The initial target of ionizing radiation within the kidney appears to be endothelial cells, leading to endothelial cell swelling. Subsequent vascular occlusion develops with resultant tubular atrophy. Electron microscopy reveals a split appearance of the capillary wall due to the mesangial interposition and widening of the subendothelial space by a nondescript fluffy material. These features are shared by hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura, suggesting a common pathogenic mechanism originating from endothelial injury. Severe disease is characterized by progressive interstitial fibrosis and the presence of interstitial inflammatory cells.

Clinical Manifestations

In general, vascular and glomerular lesions of the thrombotic microangiopathy may predominate. However, tubulointerstitial changes of varying severity are also usually present. Hypertension is commonly observed. Progression to a “chronic” form of radiation nephritis may occur if resolution of acute radiation nephritis is incomplete. These patients present with proteinuria, progressive CKD, and eventual development of ESRD several years after irradiation in the absence of an acute phase.

Treatment

Prevention is the best approach. The risk for development of radiation nephritis can be minimized by shielding of the kidneys or fractioning the total-body irradiation into several small doses during several days. No specific treatment is available for established radiation nephritis; consequently, the general approach is control of hypertension and supportive treatment of CKD.

ENDEMIC DISEASES

Balkan Nephropathy

Definition and Epidemiology

This is an endemic kidney disease confined to discrete, well-defined settlements in the Balkans (i.e., Albania, Bosnia, Croatia, Serbia, Macedonia, Romania, Bulgaria; Fig. 62.11). The spatial distribution has remained unchanged with time, and the disease affects the same endemic clusters as 50 years ago. The disease

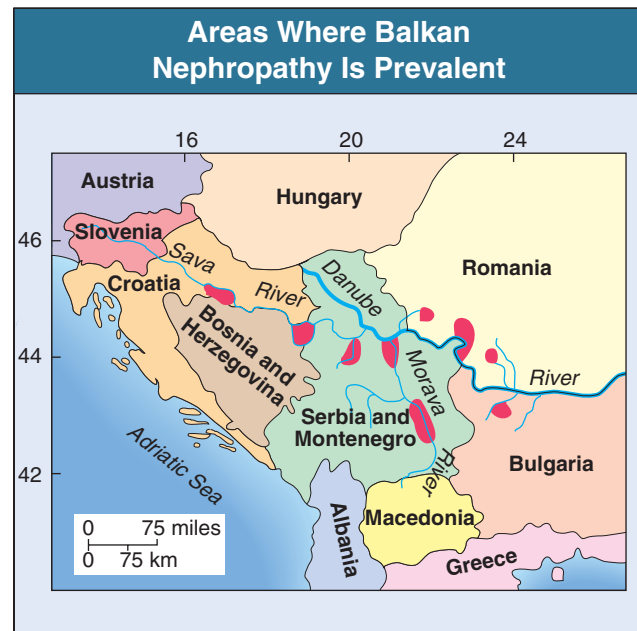

Figure 62.11 Balkan endemic nephropathy. Geographic regions where Balkan nephropathy is prevalent. The endemic areas are in red.

occurs in indigenous or immigrant individuals who have resided in an endemic area for at least 15 to 20 years and does not occur among residents who move to nonendemic areas. The clinical features of Balkan nephropathy are essentially identical to those of aristolochic acid-associated nephropathy (see Chapter 74), and recent advances in the understanding of endemic nephropathy now favor the causative role of aristolochic acid over the ubiquitous mycotoxin (ochratoxin A), which had been previously implicated.³²

Pathogenesis

Most recent studies suggest that Balkan nephropathy results from contamination of wheat flour with aristolochic acids, which are derived from the seeds of *Aristolochia clematitis*. Analysis of the renal cortex of patients with Balkan nephropathy identified DNA adducts derived from aristolochic acid.³³ Thus, the disease most likely occurs in genetically predisposed individuals who are chronically exposed to a causative factor (aristolochic acid) in the environment within endemic areas.

Pathology

The kidneys are usually of normal size early in the course of the disease. A symmetric, smooth reduction in size is observed in late-stage disease. Renal biopsy findings are characterized by proximal tubular lesions in the early stage of disease, with predominantly focal tubular atrophy, interstitial edema and sclerosis, and sometimes mononuclear cell infiltrates. Disease progression is associated with marked tubular atrophy, peritubular capillary damage, and interstitial fibrosis. Early glomerular changes are mild and focal, whereas most glomeruli are hyalinized or sclerotic in advanced stages of the disease.

Clinical Manifestations

Balkan nephropathy typically is manifested clinically in the fourth or fifth decade of life and is only rarely seen in individuals younger than 20 years. One of the first signs, detected only when

prospective monitoring is performed, is tubular proteinuria. Proteinuria is usually mild or intermittent but may increase in the advanced stages. An unremarkable urinary sediment is characteristic. Other manifestations of abnormal renal tubular dysfunction include impaired acidification, decreased ammonia and increased uric acid excretion, and urine concentrating defects with renal salt wasting, which may precede the decrease in GFR. The disease slowly progresses to ESRD.

An early feature is normochromic normocytic anemia disproportionate to the degree of renal impairment, whereas patients are usually without edema and are normotensive. Hypertension develops only with ESRD.

The increased incidence of uroepithelial carcinomas is similar to that observed in both analgesic nephropathy and aristolochic acid-associated nephropathy. Patients with macroscopic hematuria need attention and should be investigated for the presence of uroepithelial tumors.

Diagnosis

If screening by urinalysis and estimated GFR is negative, subjects should be followed up every 1 to 3 years, depending on risk factors. If abnormalities are found on screening, further evaluation is indicated; a diagnosis of Balkan nephropathy is currently made in inhabitants from endemic settlements by the criteria described in Figure 62.12.³⁴ Recent analysis of 182 patients in Serbia showed that proteinuria, urine α_1 -microglobulin, and kidney length and volume are significant predictors of Balkan nephropathy, whereas variables related to kidney failure as well as several tubular disorders (urine specific gravity, fractional sodium excretion, and tubular phosphate reabsorption) had an insignificant predictive value.³⁵

Treatment

Treatment is primarily supportive. For advancing disease with proteinuria or hypertension, ACE inhibitors or ARBs are recommended.

Diagnostic Procedures of Balkan Nephropathy

Diagnosis of Balkan nephropathy is made in inhabitants from endemic settlements using the following:

1. Epidemiologic criteria
2. Demonstration of
 - GFR decrease
 - Proteinuria generally below 1 g/24 hours
 - Microalbuminuria
 - Little urinary sediment
 - Tubular markers (renal glucosuria, increased urinary excretion of β_2 microglobulin or alpha-1-microglobulin, and N-acetyl- β -D-glucosaminidase)
 - Typical renal histology showing hypocellular cortical interstitial fibrosis decreasing from the outer to the inner cortex (if renal biopsy feasible)
3. Exclusion of other known kidney disease (e.g., chronic pyelonephritis—obstructive and atrophic, adult dominant polycystic kidney disease, glomerulonephritis)

Figure 62.12 Diagnostic procedures of Balkan nephropathy. (Modified from reference 34.)

INTERSTITIAL NEPHRITIS MEDIATED BY IMMUNOLOGIC MECHANISMS

Sjögren's Syndrome

Definition and Epidemiology

Sjögren's syndrome may be associated with chronic interstitial nephritis. The reported prevalence of renal involvement in Sjögren's syndrome has varied widely, ranging from 2% to 67%, principally owing to different definitions of kidney involvement or disease. Recent analysis of 130 patients with primary Sjögren's syndrome in a Chinese hospital showed that the incidence of chronic interstitial nephritis was 80% among all the biopsy materials.³⁶

Pathology

The lesion is characterized histologically by infiltration of lymphocytes and plasmacytes in the interstitium with tubular cell injury and, rarely, granuloma formation. This progresses to tubular atrophy and interstitial fibrosis over time. Immunofluorescence reveals granular deposits of IgG and C3 along the tubular basement membrane.

Clinical Manifestations

The clinical and biochemical manifestations of interstitial nephritis may be the presenting or only features of Sjögren's syndrome. Plasma creatinine concentration is generally only mildly elevated in association with a bland urine sediment and abnormalities in tubular function, including Fanconi syndrome, type 1 RTA, hypokalemia, and nephrogenic diabetes insipidus. Sjögren's syndrome is one of the most common causes of acquired distal (type 1) RTA in adults and the hypokalemia may be marked, resulting in a clinical presentation of severe weakness. Hypokalemia may occur in the absence of RTA, resulting from salt wasting and secondary hyperaldosteronism.

Treatment

Treatment with corticosteroids at the stage of cellular infiltration is frequently beneficial for protecting renal function. Although the renal disease has a slow and protracted course and CKD develops over time, progression to ESRD is rare.

Sarcoidosis

Definition and Epidemiology

Histologic evidence of interstitial nephritis with noncaseating granulomas is common in patients with sarcoidosis, but the frequency of clinically significant disease is low.³⁷ It may present as either an acute interstitial nephritis or a chronic interstitial nephritis.

Pathology

Renal biopsy reveals normal glomeruli; interstitial infiltration, mostly with mononuclear cells; tubular injury; and with more chronic disease, interstitial fibrosis. Whereas the classic finding is noncaseating granulomas in the interstitium, they are uncommon and nonspecific. Analysis of 18 cases with granulomatous interstitial nephritis in Glasgow showed that five cases were associated with sarcoidosis, two were associated with tubulointerstitial nephritis and uveitis, two were associated with medication, and nine were idiopathic.³⁸ Immunofluorescence and electron microscopic studies typically show no immune deposits.

Clinical Manifestations

Most affected patients have clear evidence of diffuse active sarcoidosis, although some present with an isolated elevation in plasma creatinine and only minimal extrarenal manifestations. The urinalysis, if not normal, shows only sterile pyuria or mild proteinuria.

In addition, hypercalcemia induced by increased production of calcitriol (1,25-dihydroxyvitamin D) by activated mononuclear cells (particularly macrophages) in the lung and lymph nodes occasionally results in renal problems (see the previous discussion of hypercalcemic nephropathy).

The serum ACE level is used best not as a primary diagnostic tool but as a marker of disease activity and response to therapy. A normal serum ACE level does not exclude renal disease.

Treatment

Corticosteroid therapy tends to improve renal function, although recovery is often incomplete. Rapid tapering of corticosteroid can result in relapse.

Systemic Lupus Erythematosus

Definition and Epidemiology

Interstitial nephritis with immune complexes is defined by granular deposits of immunoglobulins and complement in the tubular basement membrane, interstitium, or both. Systemic lupus erythematosus is the most common reason for this type of interstitial nephritis (Fig. 62.13), and interstitial involvement is present in half of kidney biopsy specimens in lupus. Rarely, tubulointerstitial immune complex disease may be the only manifestation of lupus nephritis.

Clinical Manifestations

The presentation may be as an acute or chronic interstitial nephritis. The possibility of interstitial involvement (without glomerular disease) is suggested by a rising plasma creatinine concentration and a bland urine sediment. Interstitial involvement may be accompanied by signs of tubular dysfunction, such as type 1 or type 4 RTA; by isolated hyperkalemia resulting from impaired distal potassium secretion; or by hypokalemia resulting from salt wasting. The potentiating effects of sodium wasting on potassium secretion include an increase in sodium delivery to the potassium secretory site in the collecting tubules and associated volume depletion with subsequent stimulation of aldosterone secretion.

Treatment

Corticosteroid therapy is usually effective in subsiding tubular dysfunction and preserving renal function.

Inflammatory Bowel Disease

Although the most frequent renal complications of Crohn's disease are calcium oxalate stones and renal amyloidosis, several cases of interstitial nephritis were reported in patients treated for chronic inflammatory bowel disease. Whereas aminosalicylates (5-aminosalicylic acid, mesalazine, and sulfasalazine) are responsible for the development of chronic nephropathy in most cases, nephrotoxicity of these reagents is exceptional (mean rate of only 0.3% per patient-year).³⁹ Nephrotoxicity most often occurs in the first 12 months of treatment with aminosalicylate, but a delayed presentation after several years has also been reported. There is no clear relationship between aminosalicylate dose and

Figure 62.13 Chronic interstitial nephritis in lupus. **A**, Interstitial nephritis observed in patients with systemic lupus erythematosus. (Periodic acid-Schiff staining; original magnification $\times 400$.) **B**, Immunofluorescence study of the same patient revealed deposition of IgG in the interstitium, in tubular cells, and along the tubular basement membrane. (Courtesy Drs. Akira Shimizu and Hideki Takano, Nippon Medical School, Tokyo, Japan.)

the risk of nephrotoxicity, suggesting that this is an idiosyncratic response. Some patients were reported to have biopsy-proven interstitial nephritis before the diagnosis of Crohn's disease.

Aminosalicylates should be withdrawn when renal impairment is manifested in a patient with inflammatory bowel disease; if this does not result in a fall in plasma creatinine, renal biopsy should be considered. Corticosteroids may be recommended when renal function does not respond to drug withdrawal.

Interstitial Nephritis in IgG4-Related Sclerosing Disease

Definition and Epidemiology

On the basis of histologic and immunohistochemical examination of various organs of patients with autoimmune pancreatitis, a novel clinicopathologic entity of IgG4-related sclerosing disease has been proposed.⁴⁰ This is a systemic disease that is characterized by extensive IgG4-positive plasma cells and T-lymphocyte infiltration of various organs (Fig. 62.14). Most reports of IgG4-related sclerosing disease have come from Japan, but it has also been described in countries in Europe as well as in the United States and Korea, suggesting that it is a worldwide entity. The incidence may be increasing, perhaps because of increased recognition.

Figure 62.14 Chronic interstitial nephritis in IgG4-related sclerosing disease. **A**, Interstitial nephritis with numerous mononuclear cell infiltrates observed in patients with autoimmune pancreatitis. Many of these cells are positive for IgG4 in typical cases. (Periodic acid–Schiff staining; original magnification $\times 200$.) **B**, CT scan of the patient revealed pancreatic swelling (arrows). (Courtesy Dr. Hiroshi Nishi, University of Tokyo, Tokyo, Japan.)

Pathology

There is tubulointerstitial nephritis with dense infiltrations of IgG4-positive mononuclear cells.

Clinical Manifestations

Clinical manifestations are observed in various organs, presenting as sclerosing cholangitis, cholecystitis, sialadenitis, retroperitoneal fibrosis, and so on. Whereas most IgG4-related sclerosing disease is most often associated with autoimmune pancreatitis, those without pancreatic involvement have also been described. The disease occurs predominantly in older men. Serum IgG4 levels are raised, and IgG4-positive cells are found in the interstitium.

Treatment

The response to corticosteroids is generally favorable.

Other Forms of Immune-Mediated Interstitial Nephritis

Primary anti-tubular basement membrane (TBM) nephritis is an extremely rare form of interstitial nephritis that usually is acute

and characterized by linear deposits of immunoglobulins and complement in the TBM together with tubular interstitial inflammation and anti-TBM antibodies in the serum. Anti-TBM antibodies may also be found in 50% to 70% of patients with anti-glomerular basement membrane nephritis and occasionally in patients with membranous nephropathy, systemic lupus erythematosus, IgA nephropathy, minimal change disease, and malignant hypertension.

OBSTRUCTIVE UROPATHY

Complete or partial urinary tract obstruction is accompanied by pathologic changes in both the tubulointerstitium and glomeruli consisting of interstitial fibrosis, tubular atrophy, and occasionally focal glomerular sclerosis. Details are discussed in Chapters 58 and 61.

VASCULAR DISEASES

Kidney disease in this category is variably termed ischemic nephropathy, renovascular disease, and nephrosclerosis. Ischemia due to intrarenal vascular involvement causes tubular atrophy, interstitial fibrosis, and cellular infiltration. Of note, chronic ischemia in the tubulointerstitial compartment also plays a crucial role in the progression of a variety of glomerular and tubulointerstitial diseases.³ For details, refer to Chapter 64.

VIRUS-ASSOCIATED CHRONIC INTERSTITIAL NEPHRITIS

Although a variety of bacterial and viral infections can be associated with acute interstitial nephritis (see Chapters 55 and 60), chronic interstitial nephritis secondary to infectious agents appears to be rare. Chronic bacterial infections can result in xanthogranulomatous pyelonephritis or renal malacoplakia (see Chapter 51).

Myeloma and the Kidney

Ashley B. Irish

Myeloma is an uncommon hematologic malignant neoplasm, accounting for 1% of total and 10% of hematologic malignant neoplasms. Whereas all ethnic groups are affected, African Americans have twice the incidence of Caucasians, and males predominate over females. It is a disease of the elderly; the median age at diagnosis is older than 65 years. The characteristic feature of myeloma is the dysregulated overproduction of immunoglobulin and especially the light-chain component, which can be nephrotoxic. Various etiologies and manifestations of acute kidney injury (AKI) are possible in myeloma (Fig. 63.1), but the major risk is to due to myeloma cast nephropathy, which is a medical emergency that requires prompt diagnosis and intervention to avoid irreversible renal failure. This chapter primarily focuses on cast nephropathy; for other renal syndromes associated with myeloma, see Chapter 10 (hypercalcemia), Chapter 26 (amyloid and light-chain deposition disease), Chapter 48 (Fanconi syndrome), Chapter 57 (nephrolithiasis), and Chapter 66 (pathophysiology of AKI).

ETIOLOGY AND PATHOGENESIS OF MYELOMA

Myeloma is an incurable B cell–derived malignant neoplasm of incompletely differentiated plasma cells that have two prominent features, increased production of monoclonal immunoglobulin and bone destruction. Normally, plasma cells derive from mature uncommitted B cells and after antigen stimulation undergo heavy-chain class switching from μ (IgM) expression to α , δ , ϵ , or γ . Whole immunoglobulin requires the intracellular assembly of two heavy chains and two light chains, κ or λ , to derive whole IgG, IgA, IgD, and IgE. Light chains are normally excreted in slight excess, with a κ : λ ratio of approximately 2:1. In myeloma, a clone of cells secretes excessive quantities of a specific immunoglobulin or light chain (the paraprotein or M protein). The genetic and somatic abnormalities underlying this malignant clone are complex and remain incompletely understood but have important implications for prognosis and treatment.¹ Both dysregulation of cell cycling and impaired apoptosis account for their progressive and dysfunctional accumulation within the bone marrow and occasionally other organs. Plasma cells express little surface immunoglobulin and are recognized by surface expression of CD38 and CD138; they normally reside only in the bone marrow. In myeloma, unrestrained plasma cell growth is supported by a complex milieu of autocrine and paracrine cytokines, especially interleukin (IL)–6. These cytokines are secreted from stromal cells, endothelial cells, or osteoclasts and maintain myeloma cell growth, survival, and migration; they

also contribute to local organ dysfunction (e.g., bone resorption, fracture, and anemia).²

ETIOLOGY AND PATHOGENESIS OF RENAL DISEASE

Free light chains circulate as monomers (predominantly $\kappa \approx 25$ kd) and dimers (predominantly $\lambda \approx 50$ kd) with a very short half-life (2 to 6 hours) due to free glomerular filtration, whereas the much larger whole immunoglobulin circulates intact for several weeks. The filtered free light chain is reabsorbed in the proximal tubule cell (PTC) by receptor-mediated endocytosis after binding with the glycoprotein receptor cubilin (Fig. 63.2).³ Light chains in excess can induce an inhibitory effect on endocytosis *in vitro* and are associated with lysosomal overload and rupture, releasing enzymatic contents into the cytosol, manifested histologically by evidence of crystallization, vacuolation, and desquamation of the PTC. Endocytosis of light chains induces the release of the proinflammatory cytokines IL-6 and IL-8 and monocyte chemoattractant protein 1 through the activation of nuclear factor κB in the PTC.⁴ This mechanism suggests that light-chain overload induces factors promoting interstitial injury and fibrosis, as described in other proteinuric states. Light chains may also be cytotoxic to the PTC by direct DNA injury and the induction of apoptosis.⁵ A less common manifestation of PTC injury is the Fanconi syndrome, which is invariably associated with specific variant κ light chains and often with pathologic evidence of crystalline inclusions.⁶

Injury to the PTC allows escape or overflow of the light chain to the distal nephron, where it can interact with the Tamm-Horsfall protein (THP) secreted by the cells of the thick ascending loop of Henle. Variations in the specificity of the binding region of different light chains modify the affinity of the light chain for binding with THP, which could in part explain the variable nephrotoxicity of light chains.⁷ This specificity of the individual light chains for THP was illustrated by the finding that the intraperitoneal instillation of light chains isolated from humans with specific renal light chain–associated disease induces the same renal injury in animals.⁸ Whereas renal injury occurs only in the presence of urinary light chains, not all light chains are associated with injury, and neither the amount nor type of urinary light chain correlates with the severity of cast formation. Nevertheless, in general, the higher the urinary excretion of light chains, the greater the risk for renal failure.^{9,10} In addition to light chain–specific factors, tubular solute composition and tubular

Figure 63.1 Etiology of renal injury and clinical manifestations. LCDD, light-chain deposition disease; NSAIDs, nonsteroidal anti-inflammatory drugs.

Etiology of Renal Injury and Clinical Manifestations		
Cause		Manifestation
Prerenal		
Volume depletion	Hypercalcemia Gastrointestinal losses (nausea and vomiting) Sepsis	Polyuria and polydipsia Hypotension Fever
Hemodynamic	Hemodynamic from NSAIDs	Oliguria, hyperkalemia
Other	Hyperviscosity (IgA, IgG ₃) Hyperuricemia	Mental state alterations Tumor lysis
Renal

flow rates modulate the risk for cast formation. In animals, urinary acidification, furosemide, and urinary sodium and calcium concentration may affect the tendency to increased binding or aggregation of light chains with THP; colchicine may reduce this tendency in animals but not in humans.^{11,12} The formation and passage of casts distally can occlude the tubule and allow intratubular obstruction, with rupture and even backflow of contents (Fig. 63.3).

EPIDEMIOLOGY

Most myeloma presents *de novo*, although a small number evolve from patients with monoclonal gammopathy of undetermined significance (MGUS) each year. In Europe, approximately 50 cases per million occur annually. In patients with newly diagnosed myeloma, the prevalence of IgG, IgA, IgD, and free light chain–only myeloma was 52%, 21%, 2%, and 16%, respectively.⁹ IgM and IgE myeloma are extremely uncommon. Approximately 70% of patients with myeloma also have a urinary M protein. At the time of diagnosis of myeloma, up to 50% of patients have evidence of impaired renal function judged by increased serum creatinine; around 25% present with serum creatinine concentration above 2 mg/dl (177 μ mol/l).^{9,10} In unselected series, 2% to 10% of patients present with severe

renal failure requiring dialysis; this figure is higher in series reported from renal units. In contrast to the general distribution of M protein types in myeloma, light-chain and IgD myeloma are particularly associated with the risk of renal disease, being present in nearly 50% of patients with severe renal disease requiring dialysis.¹³

CLINICAL PRESENTATION

Most patients present with constitutional symptoms (fatigue, weight loss) and skeletal pain, especially back pain. Renal impairment is common and has a variety of causes (see Fig. 60.1). In a smaller proportion of patients, renal failure is the presenting manifestation of myeloma, and the diagnosis of myeloma is made or suggested by the renal biopsy findings. In general, these patients have more advanced disease with high morbidity and mortality.¹³ Renal findings are nonspecific, usually with kidneys of normal size and bland urine. Urinary protein excretion may be marked because of the presence of light chains, whereas urinary dipstick may indicate only small amounts of protein because this measures albumin. Normal or elevated ionized calcium, decreased serum anion gap, lytic bone lesions on radiographic examination, hypogammaglobulinemia or reductions in levels of other immunoglobulin classes (immune paresis), abnormal serum free light chain ratio, significant cytopenias, and blood film changes (plasma cells or leukoerythroblastic film) are suggestive of myeloma. Clinical and laboratory findings that may distinguish myeloma cast nephropathy from other monoclonal immunoglobulin deposition diseases are listed in Figure 63.4 and discussed in Chapter 26.

PATHOLOGY

Histologic examination of the kidney in myeloma has diagnostic and prognostic utility, although it is not always required, and the risk of complications after biopsy may be increased. Biopsy is useful for the initial evaluation of AKI and to guide treatments designed to reverse AKI. Figure 63.5 lists the likely findings and prevalence of renal injury noted at histologic or autopsy sampling. Myeloma cast nephropathy, the most common histologic finding, occurs in 30% to 50% of patients (Figs. 63.6 and 63.7A). Myeloma cast nephropathy is characterized by many distal tubular casts that are strongly eosinophilic and consist of the monoclonal light chains and laminated THP, which often appear

Figure 63.3 Renal injury caused by light chains. Sites (shaded boxes) where light chains injure the tubule. In the proximal tubule, there is direct tubular cytotoxicity. In the distal tubule, there is cast injury.

fractured after fixation. Casts promote local inflammation with giant cell formation.^{14,15} In 30% of cases, cast formation may not be prominent despite extensive tubulointerstitial injury (Fig. 63.7B, C).¹⁶ Glomeruli are usually spared unless there is associated light-chain deposition disease or amyloidosis (see Chapter 26).

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The International Myeloma Working Group (2003) diagnostic criteria for symptomatic myeloma require (1) detection and quantification of a monoclonal protein by serum electrophoresis (SEP) and characterization by immunofixation electrophoresis (IFE), (2) bone marrow (clonal) plasma cells or biopsy-proven plasmacytoma, and (3) demonstration of any end-organ damage not otherwise explained by other pathologic processes (including hypercalcemia, renal failure, anemia, and lytic bone disease).¹⁷ The monoclonal M protein is the key abnormality required for diagnosis, and 97% of patients have an intact immunoglobulin or a free light chain by SEP and IFE. The quantity of the M protein is estimated from the SEP and may be used both for diagnosis and to monitor response to therapy. Urinary light chain (Bence Jones protein) concentration is determined from a concentrated sample, but despite this, light chains may still be below the level of detection by IFE. The new specific quantitative free light chain assay (which measures only light chains not bound to whole immunoglobulin) for both urine and serum is significantly more sensitive than SEP and IFE alone and is an automated assay that allows rapid diagnosis.¹⁸⁻²⁰ An abnormal

monoclonal free light chain clone increases the specific light chain fraction and may suppress the other light chains, which alters the normal ratio of free light chains (0.26-1.65 $\kappa:\lambda$) to reflect the oversecretion of the abnormal light chain clone (e.g., <0.26 for λ free light chain clone, >1.65 for κ clone). The normal serum levels of free light chains are very low (7 to 13 mg/l), but in patients with impaired renal function, accumulation of both (κ and λ) free light chains is due to reduced excretion, and the ratio generally remains within the normal range. However, because λ free light chains tend to circulate as dimers, their clearance is reduced more than the monomeric κ free light chains, and this may alter the ratio such that the use of an extended reference range of 0.37 to 3.1 improves diagnostic sensitivity for myeloma to 99% with 100% specificity in the presence of renal failure.²⁰ The absolute value of the serum monoclonal light chains is of lesser importance in diagnosis. In general, patients with renal failure without myeloma have polyclonal increases in free light chains on the order of 10 to 20 times normal; but in biopsy-proven cast nephropathy, the ratios are highly abnormal, and the absolute increases in free light chains are on the order of 100 to 200 times normal and have values above 500 mg/l (usually >1000 mg/l) at presentation (Fig. 63.8).²⁰ Measurement of serum free light chains has significant advantages over SEP and IFE and is now incorporated into international clinical guidelines for the diagnosis and management of myeloma.²¹

Diagnostic difficulties can arise in elderly patients who are evaluated for newly diagnosed renal impairment and routine SEP reveals an M protein. Approximately 3% of the population older than 70 years will have a serum M protein, most consistent

Differentiating Features of Myeloma Kidney and Other Monoclonal Immune Deposition Diseases		
	Myeloma Kidney	Other MIDDs
Proteinuria	<3 g/l	>3 g/l
Hematuria	Rare	LCDD, occasional Amyloidosis, rare
Hypercalcemia (or normal corrected calcium)	Common	Absent
Hypertension	Uncommon	LCDD common Amyloidosis uncommon
Cytopenias	Anemia very common Leukopenia and thrombocytopenia, occasional	Uncommon
Immunoparesis*	Very common	Uncommon
Lytic bone lesions	Very common	Absent
Renal impairment	Common	Common
Heavy chain	IgA, IgD, IgG	None
Type of light chain	Either	Amyloid $\lambda > \kappa$ LCDD $\kappa > \lambda$
Urinary light-chain excretion	Higher	Lower

Figure 63.4 Clinical features of myeloma kidney versus monoclonal immunoglobulin deposition disease. LCDD, light-chain deposition disease; MIDDs, monoclonal immunoglobulin deposition diseases. *Defined as a reduction in the nonparaprotein globulin fractions.

Renal Pathology in Patients with Multiple Myeloma	
Histological Finding	Prevalence
Myeloma kidney (<i>Myeloma cast nephropathy</i>)	30%-50%
Interstitial nephritis/fibrosis without cast nephropathy	20%-30%
Amyloidosis	10%
Light chain deposition disease	5%
Acute tubular necrosis	10%
Other (urate nephropathy, tubular crystals, hypercalcemia, FSGS)	5%

Figure 63.5 Renal pathology in patients with multiple myeloma. FSGS, focal segmental glomerulosclerosis. (From references 25, 56-61.)

Histologic Features of Myeloma Kidney
Many eosinophilic, often fractured casts (medullary portion of the distal nephron predominantly)
Intratubular and interstitial macrophages and giant cells in response to casts
Interstitial inflammation, fibrosis, tubular atrophy, crystalline inclusions
Minimal glomerular abnormality
Minimal or no vascular changes

Figure 63.6 Histologic features of myeloma cast nephropathy.

with MGUS. A diagnosis of MGUS is more likely if the serum level of the M protein is low (<3 g/dl), urinary light chains are absent or very low (<1 g/24 h), and there is a normal free light chain ratio with the absence of end-organ injury (no lytic lesions, <10% plasma cells on bone marrow aspirate).²² This distinction is important because most patients with MGUS will die of an unrelated disease, and only 1% a year progress to myeloma.²³ The majority of renal disease in patients with MGUS is unrelated to the M protein,²⁴ although rare cases of focal segmental glomerulosclerosis have been associated with a dysproteinemia.²⁵ Evidence supportive of alternative causes of the renal disease (most commonly diabetes and vascular disease) along with a period of observation may clarify the significance of the M protein, although renal or bone marrow biopsy may be required when diagnostic uncertainty persists.

NATURAL HISTORY

The majority of patients with renal impairment at presentation will show resolution of these predominantly functional changes with therapeutic measures that include withdrawal of nephrotoxins, rehydration, treatment of hypercalcemia, treatment of sepsis, and reduction in light-chain load with chemotherapy. Response to treatment with improvement in renal function is associated with improved clinical outcomes.²⁶ Reversibility occurs more frequently with lesser degrees of initial renal impairment, lower light-chain excretion, and hypercalcemia. Although renal function improves in the majority of patients, approximately 10% of patients presenting with renal impairment at diagnosis may require dialysis. Patients requiring dialysis have reported rates of recovery of renal function as low as 5% to 15% or, more recently, up to 30%.²⁷ This recovery sometimes occurs many months after presentation.

TREATMENT

There are three key issues in the management of myeloma cast nephropathy. The first is to suspect and to diagnose myeloma in the differential diagnosis of AKI, and the inclusion of serum free light chain measurement for routine evaluation of otherwise unexplained AKI in appropriate clinical circumstances is essential. This is because renal injury in myeloma is directly related to free light chain excess, and the increased sensitivity and specificity of free light chain measurement along with its rapid availability may implicate or refute myeloma as a likely diagnostic possibility days in advance of standard tests (SPE, IFE) or renal biopsy. Early diagnosis is crucial to allow implementation of the second strategy, which is to prevent or to reverse oliguria by rapid identification and management of possible contributing factors to renal impairment, which are present in around 50% of patients. Hypercalcemia, sepsis, and nonsteroidal anti-inflammatory agents are the most common precipitants. Intravenous volume expansion is helpful to increase glomerular filtration, to reduce single-nephron light-chain concentration, and to increase tubular flow. The use of furosemide to promote diuresis should be avoided as this may favor cast formation. There is no clinical evidence of the superiority of sodium bicarbonate over sodium chloride for volume expansion, although prevention of urinary acidification is in theory desirable and in severe renal failure may be necessary for management of metabolic acidosis. The maintenance of a high fluid intake (3 l/day) with water after initial volume correction and restoration of urine output with intravenous crystalloid is recommended

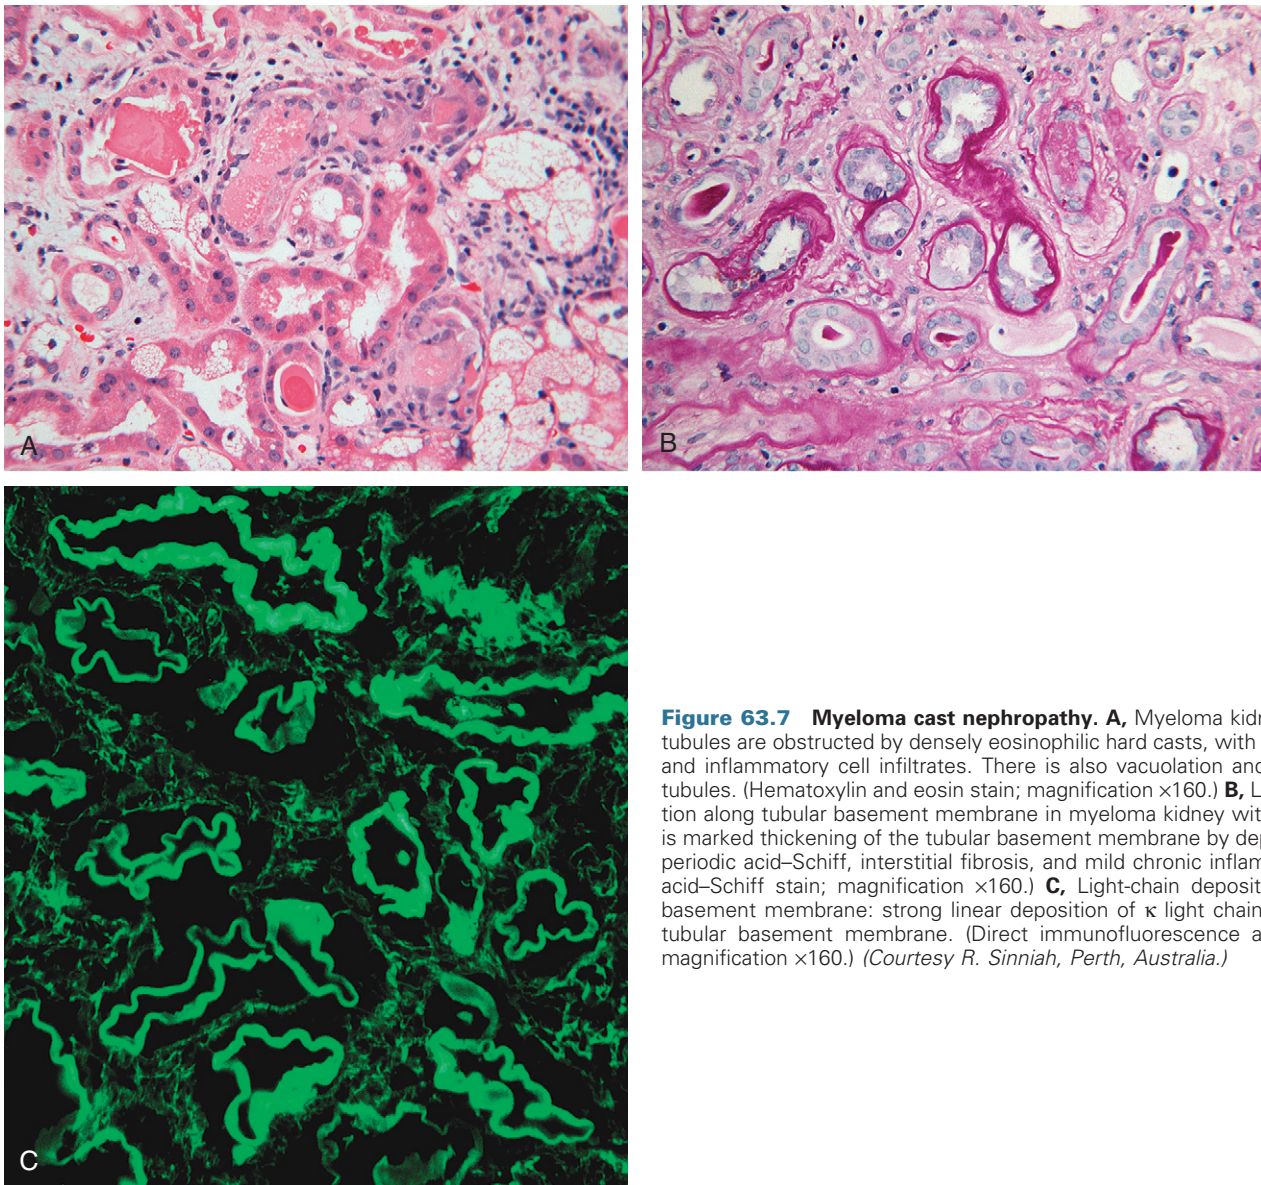

Figure 63.7 Myeloma cast nephropathy. **A**, Myeloma kidney. Many dilated tubules are obstructed by densely eosinophilic hard casts, with giant cell reaction and inflammatory cell infiltrates. There is also vacuolation and degeneration of tubules. (Hematoxylin and eosin stain; magnification $\times 160$.) **B**, Light-chain deposition along tubular basement membrane in myeloma kidney without casts. There is marked thickening of the tubular basement membrane by deposits positive for periodic acid–Schiff, interstitial fibrosis, and mild chronic inflammation. (Periodic acid–Schiff stain; magnification $\times 160$.) **C**, Light-chain deposition along tubular basement membrane: strong linear deposition of κ light chain in the thickened tubular basement membrane. (Direct immunofluorescence anti- κ light chain; magnification $\times 160$.) (Courtesy R. Sinniah, Perth, Australia.)

to maintain high urine flow rates. Hydration before the use of contrast agents for radiologic or other procedures is essential.^{28,29}

The third key requirement is the rapid reduction of free light chains in the serum by chemotherapy and, in patients with proven cast nephropathy, by enhanced dialysis (see later discussion) or in some cases plasma exchange. The immediate commencement of high-dose dexamethasone (40 mg daily) is recommended as plasma cells are highly responsive to corticosteroids, which induce rapid apoptosis and lowering of light-chain concentration. The addition of newer chemotherapy strategies (see later discussion) with high immediate light-chain lowering effects in combination with corticosteroids is also critical to rapid response.^{30,31} The routine addition of plasma exchange to conventional treatment did not improve either recovery from renal failure or patient survival.²⁷ The large volume of distribution of light chains (which freely cross cell membranes) is not well suited to plasma exchange; however, in some circumstances, its use as an adjunct with chemotherapy may be considered beneficial.³² The use of a new Polyflux dialysis membrane (HCO

1100, Gambro Scientific Research), with a high cutoff up to 50 kD, in conjunction with early chemotherapy has been shown to reverse renal failure in association with the rapid reduction in circulating free light chains in patients with cast nephropathy.³³ The optimal use of this membrane is under clinical trial and may differ according to the type of light chain, response to chemotherapy, use of convective therapies, and extended duration of dialysis.³⁴ A suggested algorithm for management of myeloma with AKI is shown in Figure 63.9.

Chemotherapy

Although myeloma is incurable, with a median survival of all patients around 3 years, chemotherapy will induce clinical improvement by control of the underlying disease. Until recently, no therapy had proved superior to cyclical melphalan and prednisone. The use of melphalan in patients with renal impairment (glomerular filtration rate <30 mL/min) requires dose adjustment to avoid the risk of significant hematologic toxicity.³⁵ Autologous stem cell transplantation (ASCT) significantly extends survival

Figure 63.8 Serum free light chain ratio and values in normal individuals, patients with renal impairment, and light-chain myeloma. FLC, free light chain; IFE, immunofixation electrophoresis; SPE, serum protein electrophoresis; LCMM, light chain multiple myeloma. (Reprinted with permission from reference 20.)

and is now the treatment of choice for eligible patients.³⁶ Even patients with renal impairment and on dialysis may be suitable for ASCT, although increased morbidity and mortality are recognized.^{37,38} For the very elderly, chemotherapy selection is dependent on comorbidity, and melphalan-prednisone or dexamethasone-thalidomide may be useful. Close multidisciplinary management and discussion with hematology and oncology services are required to individualize decision-making because of the rapid advances in this area.³⁹ Bortezomib, a reversible proteasome inhibitor whose clearance is independent of renal function, has been successfully and safely used in patients with severe degrees of renal failure and myeloma without significant toxicity and may be the agent of choice for rapid reduction of light chains in combination with dexamethasone and hemodialysis.³⁰ Thalidomide and lenalidomide are increasingly used first or as consolidation or maintenance therapy. Side effects of thalidomide include peripheral neuropathy, venous thrombosis, and teratogenicity. Preliminary data support use of thalidomide in patients with relapsed or refractory myeloma and renal failure, without need for dose alteration,⁴⁰ although concerns about hyperkalemia have been raised.⁴¹ The newer and more potent agent lenalidomide may have reduced neurotoxicity; however, its use in renal failure is less well established, and myelosuppression may be more common in patients with reduced glomerular filtration rate.⁴²

Infection and progression of disease remain the major impediments to survival, especially within the higher risk end-stage

renal disease (ESRD) group. Median survival in recent ESRD series with conventional therapies before ASCT was only 4 to 8 months; however, survival of up to 5 years is reported in selected cases of ESRD managed with ASCT.⁴³

Adjunctive Therapies

Patients with CKD or ESRD and myeloma respond to erythropoiesis-stimulating agents, and these should be used along with other hematopoietic agents including granulocyte colony-stimulating factor as required, although frequent transfusion may be necessary early in the disease.⁴⁴ Intravenous bisphosphonates rapidly correct hypercalcemia and are preferred to furosemide (which may aggravate tubular light-chain injury) and in the longer term reduce bone fracture.⁴⁵ However, there are several reports of toxicity (acute tubular necrosis, proteinuria) with high dose or rapid infusion of pamidronate and zoledronic acid; reduced doses (pamidronate, 30 to 60 mg; zoledronic acid, 2 to 4 mg) and slower infusion rates are recommended.^{46,47} Replacement of profound immunoglobulin deficiency with regular intravenous immune globulin (IVIG) has been proven to reduce infectious complications in stable treated myeloma patients but is not widely adopted although recommended.⁴⁸ Caution is required to avoid further AKI due to the hyperosmolality of IVIG because renal impairment and diabetes represent known risk factors for this complication.⁴⁹

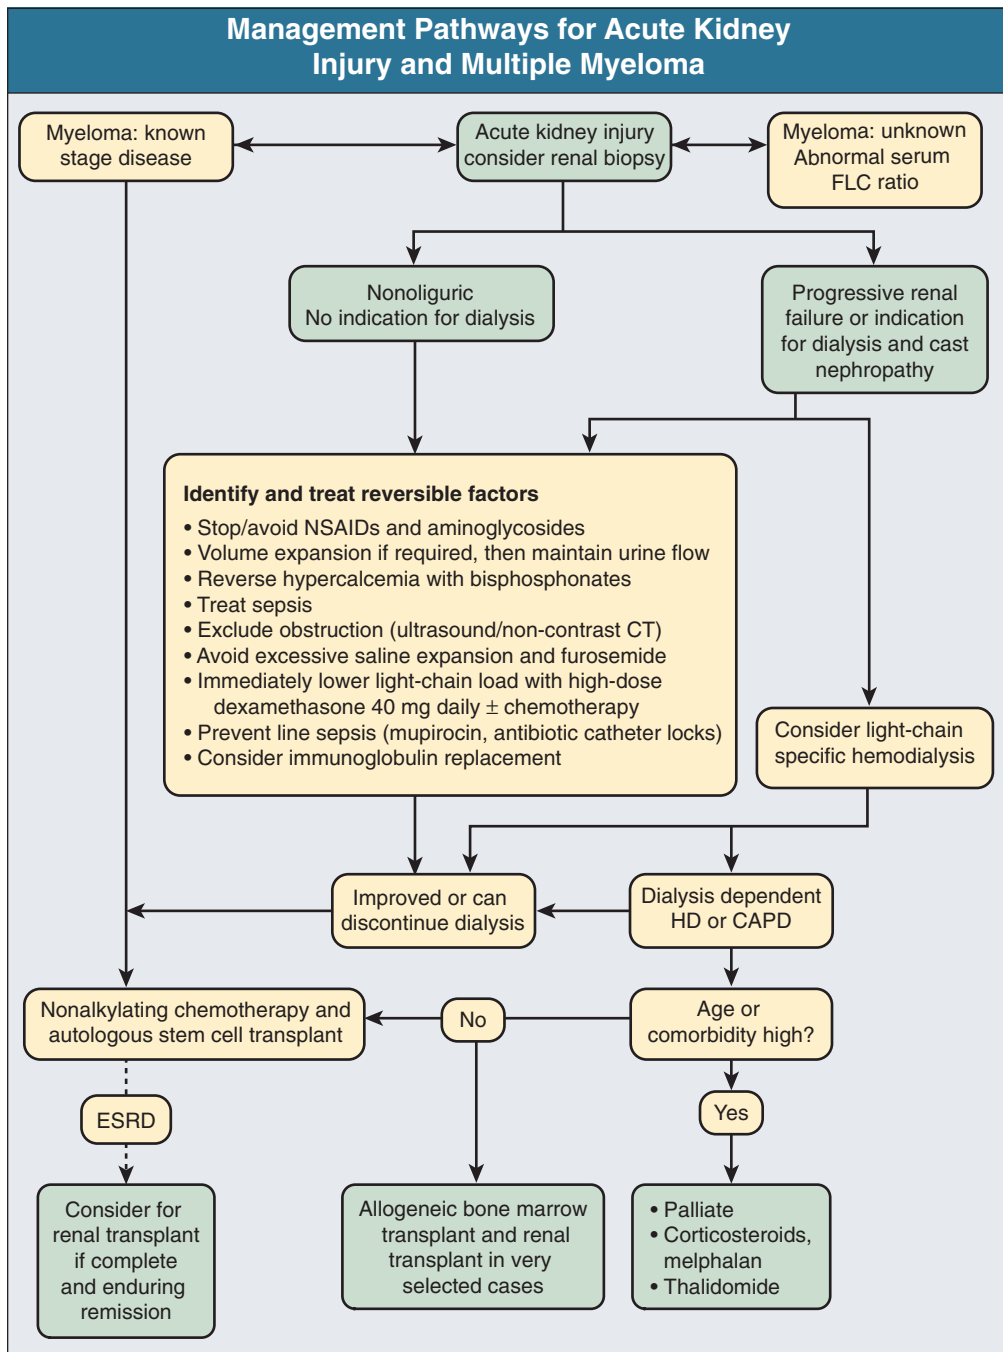

Figure 63.9 Management of myeloma and AKI. CAPD, continuous ambulatory peritoneal dialysis; CT, computed tomography; ESRD, end-stage renal disease; FLC, free light chain; HD, hemodialysis; NSAIDs, nonsteroidal anti-inflammatory drugs.

Dialysis and Transplantation

Where renal replacement therapy is required long term, both hemodialysis and peritoneal dialysis have been successfully used, and there are no data to indicate that outcome is influenced by dialysis modality. Choice of long-term therapy requires individual assessment of patient circumstances. The majority of studies support the use of dialysis, although survival is substantially reduced and early mortality (30%) is high in this group due to the severity of tumor burden and the high rates of sepsis.⁵⁰⁻⁵² Aggressive measures to reduce risk of systemic infection by antibiotic line locking or mupirocin at exit sites and the use of IVIG replacement should be routinely considered because a depen-

dency on central venous catheters for dialysis, plasma exchange, and chemotherapy is often required initially. The timing of placement of a permanent arteriovenous fistula requires an individualized risk assessment because it may be several months before irreversibility of renal failure and a response to chemotherapy are proven. Renal transplantation has a high risk of disease recurrence in the allograft and patient mortality, and given the incurability of the disease, it has rarely been appropriate.⁵³ Most recently, several cases of allogeneic bone marrow and renal allograft transplantation have been reported, demonstrating the ability to induce allograft tolerance in haploidentical pairs.⁵⁴ This treatment is limited in availability and suitability for the majority of patients. The use of renal transplantation after

successful induction therapy and ASCT is unknown but may be suitable for younger patients when disease remission by standard criteria and normalization of the serum free light chain ratio are achieved. ASCT itself has been reported to be associated with recovery of renal function when the duration of dialysis is less than 6 months.^{43,55}

Thromboembolic Renovascular Disease

Barbara A. Greco, Jamie P. Dwyer, Julia B. Lewis

Renal arterial and venous thromboembolic disease presents as a wide variety of clinical syndromes, ranging from vascular catastrophe with acute renal infarction to progressive decline in renal function due to chronic renal ischemia. Appropriate imaging allows accurate and timely identification of renal infarction, renal artery or venous thrombosis, and other renovascular abnormalities.

Thrombotic microangiopathies are discussed in Chapter 28, and renovascular hypertension and atherosclerotic ischemic renal disease are discussed in Chapter 37.

NORMAL ANATOMY

Renal Artery

The anatomic considerations that affect the clinical outcome of renal arterial thromboembolic events include the size of the vessel involved, from the main renal artery and the branch vessels to the arterioles and glomerular capillaries, and the condition of the collateral blood supply. In most individuals, the kidney has a single artery ranging in diameter from 3 to 7 mm. The incidence of multiple renal arteries is about 30%.

Acute occlusion of the renal artery may result in sudden and irreversible renal infarction, particularly if there is a single vessel with inadequate collateral circulation. In the setting of chronic renal artery occlusive disease, such as might exist on a background of atheromatous renovascular disease, the collateral circulation may be more extensively developed.

The main collateral vessels to the kidney include the suprarrenal, the lumbar, and the ureteral vessel complexes, which can maintain renal parenchymal viability in the face of main renal arterial occlusion. The collateral circulation to the kidney is depicted in [Figure 64.1](#). In a study examining 301 aortograms, the adrenal arteries supplied collateral circulation to the kidney in 60% of cases, the lumbar in 55%, the ureteric in 15%, and the gonadal in 13%.¹ The factors determining the development and caliber of these vessels are poorly understood but are likely to relate to individual anatomy, state of the aorta, rate of progression of main renal artery narrowing, and condition of the intrarenal perforating arteries.

Renal Vein

Renal veins begin in the subcapsular region of the kidney. These stellate veins communicate with perirenal and cortical venous channels and empty into interlobular veins that drain into arcuate veins. The venae rectae drain the pyramids and join the arcuate veins. Arcuate veins leave the renal parenchyma through interlobar vessels, converging into four to six trunks near the

hilum of the kidney ([Fig. 64.2](#)). The main renal veins empty into the inferior vena cava; the left renal vein is three times longer than the right (7.5 cm versus 2.5 cm). The left renal vein traverses behind the splenic vein and body of the pancreas before it crosses in front of the aorta near its termination in the inferior vena cava. The left renal vein collects the flow from the left ureteral, gonadal, adrenal, and inferior phrenic veins. In Gerota's fascia, the perirenal venous network communicates with the retroperitoneal collateral veins from the lumbar, azygos, and tributaries of the portal system.^{2,3}

THROMBOEMBOLIC RENOVASCULAR DISEASE

Thromboembolic renovascular disease results in disruption of normal renal blood flow, leading to either renal ischemia or overt infarction. The caliber and type of vessels involved (artery, arteriole, vein) as well as whether one or both kidneys are affected determine the clinical presentation ([Fig. 64.3](#)).

THROMBOEMBOLIC ISCHEMIC RENAL DISEASE

Ischemic renal disease due to atherosclerotic renovascular disease is discussed in Chapter 37. On occasion, thrombosis of the renal artery or branch vessels occurs acutely and without overt renal infarction, providing a clinical opportunity for renal salvage. The clinical settings in which this might occur include spontaneous thrombosis of atherosclerotic renal artery occlusive disease, spontaneous dissection of the aorta involving the origin of the renal artery, dissection of the renal artery itself, and as a consequence of aortic or renal artery interventions including endovascular stenting.

The clinical presentation of renal artery or branch vessel thrombosis without infarction often involves acceleration of hypertension due to renin release, worsening renal function, and even anuria if all of the functioning renal mass is involved. Patients may develop volume overload, pulmonary edema, and symptoms of uremia.

The clinical evaluation of the patient includes ruling out overt renal infarction and defining renal parenchymal viability despite main renal or branch vessel thrombosis. This can be achieved by demonstrating a nephrogram on delayed venous-phase imaging by conventional renal arteriography, computed tomographic angiography (CTA) or contrast-enhanced computed tomography (CT), magnetic resonance angiography (MRA) with gadolinium enhancement, or nuclear isotope scintigraphy. The diagnostic approach is complicated in the setting of reduced renal function because of the concern of nephrotoxicity from radiocontrast dye. In addition, the use of gadolinium with MRA is contraindicated if glomerular filtration rate (GFR) is below

Figure 64.1 Renal collateral circulation. Diagrammatic representation of the potential collateral arterial vessels to the kidney.

30 ml/min because of the risk for nephrogenic systemic fibrosis.

Treatment involves assessment of the risks versus potential benefits of heroic revascularization procedures. The status of the contralateral kidney and overall residual renal function (RRF) should be weighed against the retrieval of the additional renal function from the ischemic kidney. The ischemic kidney's length and baseline function before thrombosis determine the potential benefits of renal revascularization. The cardiac and anesthesia risk from the intervention, such as surgical thrombectomy or bypass, has to be considered. Last, the intervention should be delayed until the clinical and renal status of the patient has recovered from any transient insults, such as acute kidney injury (AKI), decompensated pulmonary edema, congestive heart failure (CHF), myocardial infarction, and uremia.

Renal function can be salvaged by renal artery surgical revascularization and endovascular stenting in patients with dialysis-dependent renal failure due to occlusive renovascular disease.⁴⁻⁶ Predictors of renal recovery are listed in Figure 64.4 and include preserved renal size, evidence of a renal “blush” or nephrogram by imaging, recent loss of GFR, and recent baseline creatinine concentration below 3 mg/dL.⁷ Figure 64.5 shows thrombosis of a renal artery within a stent placed 1.5 years previously for atherosclerotic renal artery stenosis in a patient with a single functioning kidney. The patient presented with anuric AKI. Percutaneous thrombolytic therapy and renal artery angioplasty restored renal perfusion and renal function.

RENAL INFARCTION

When abrupt interruption of renal blood flow occurs without adequate collateral blood supply, renal infarction occurs. Renal infarction may involve the entire kidney or small areas of the cortex or medulla. Both arterial and venous thrombosis and renal

Figure 64.2 Renal vein anatomy. **A**, There is extensive communication between the renal venous plexus and lumbar, gonadal, and adrenal veins, which provide alternative outflow in the setting of renal vein thrombosis, particularly on the left. **B**, Transverse section of the kidney showing relative position of vascular structures in the renal pelvis. (From reference 8.)

Predictors of Recovery of Renal Function in Renal Artery Occlusion

Preserved renal size (>7–8 cm)
Recent baseline serum creatinine < 3 mg/dl (284 μ mol/l)
Recent rapid loss of GFR
Nephrogram visible on delayed or venous phase imaging
Distal reconstitution of occluded renal artery

Figure 64.4 Predictors of recovery of renal function in renal artery occlusion. GFR, glomerular filtration rate.

artery embolism can cause renal infarction. Unlike thrombotic occlusion of a long-standing stenosis, acute vascular occlusion is often symptomatic. The most common presenting signs and symptoms include loin, flank, or abdominal pain; microscopic hematuria; and transient proteinuria (Fig. 64.6). Transient or accelerated hypertension may occur secondary to abrupt release of renin from the infarcted segment. Some cases may be asymptomatic but are noted as enhancing or functional defects on renal imaging. When bilateral occlusion of both kidney arteries or infarction of a single functioning kidney occurs, the patient presents with oliguric or anuric AKI. AKI is not uncommon, even when infarction is due to renal embolism rather than arterial thrombosis. Systemic signs of renal infarction include leukocytosis, fever, and elevations of lactate dehydrogenase, transaminases, creatine kinase, and alkaline phosphatase.⁹

Diagnosis

A high clinical suspicion is required for diagnosis. CT with the intravenous administration of contrast material is the imaging modality of choice and delineates those areas of the renal cortex that are not perfused. Other potential imaging techniques include MRA (with gadolinium if GFR remains above 30 ml/min or as time-of-flight or phase-contrast imaging) and nuclear renal scan with dimercaptosuccinic acid (DMSA). When the entire kidney is underperfused, it is often difficult to determine whether there may be salvageable renal parenchyma. Studies in experimental animals with acute renal artery occlusion have shown that the collateral circulation can maintain renal viability for up to 3 hours after occlusion.¹⁰ In patients with underlying atherosclerotic renovascular disease, collateral vessels may be better developed and renal viability may be maintained for days to weeks. In these subjects, urgent arteriography to identify the location of the arterial thrombosis or embolus may allow percutaneous or surgical revascularization.

Etiology

The most common causes of renal infarction are trauma, renal artery embolism, and iatrogenic complications of endovascular procedures (Fig. 64.7). Spontaneous renal artery thrombosis is most often associated with atherosclerotic disease of the aortic or renal arteries, but other vascular anomalies include fibromuscular dysplasia, Marfan syndrome, and Ehlers-Danlos syndrome with associated dissection or aneurysms. Less common causes of infarction include hypercoagulable states, most commonly nephrotic and antiphospholipid syndromes; inflammatory diseases of the retroperitoneum or aortorenal vasculature; and thrombotic microangiopathies (TMAs).

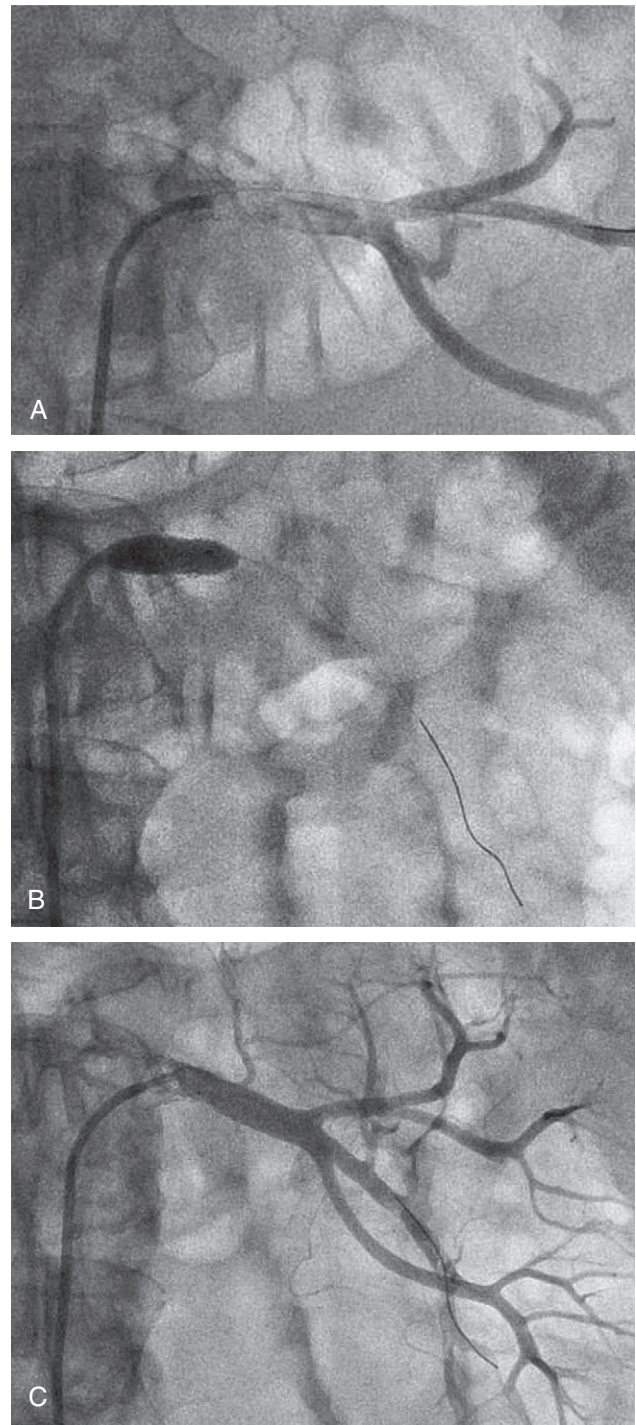

Figure 64.5 **A**, Thrombosis of renal artery within a previously placed stent. After tissue plasminogen activator thrombolytic infusion, recanalization allowed passage of a guide wire. **B**, Percutaneous renal artery balloon angioplasty of in-stent stenosis. **C**, Reperfusion of renal artery and kidney after percutaneous transluminal renal angioplasty.

Thrombosis due to Trauma

Traumatic injuries to the renal arteries make up 1% to 4% of all nonpenetrating abdominal trauma. Classically, kidney trauma results from a deceleration injury, such as a fall from a great height with an upright landing on impact. This results in stretching of the renal arteries as the kidneys continue downward after the rest of the body has stopped. The subsequent stretching and recoiling of the renal arteries can result in acute thrombosis,

Signs and Symptoms of Renal Infarction
Abdominal or flank pain
Leukocytosis
Fever
Hematuria
Elevations of serum LDH, transaminases, CK
Acceleration of preexisting hypertension or new onset hypertension
AKI
Incidental finding of perfusion defects on enhanced renal imaging

Figure 64.6 Signs and symptoms of renal infarction. AKI, acute kidney injury; CK, creatine kinase; LDH, lactate dehydrogenase.

which is typically bilateral. Direct blunt trauma to the loin or flank regions associated with motor vehicle crashes, street fights, and sports injuries can also result in renal artery thrombosis.

Evidence of lumbar vertebral injury should raise suspicion in the emergency department for renovascular trauma. Even when it is diagnosed early, the success rate for renal revascularization after trauma to the renal vessels remains low, between 0% and 29%.¹¹ Injuries to the renal pedicle that result in diminished perfusion to a single functioning kidney or to both kidneys require rapid intervention, and endovascular stabilization of renal blood flow may be helpful as a bridge to more definitive renal revascularization.

Thrombosis due to Hypercoagulable Disorders

Clotting disorders, such as protein C or protein S deficiency, antithrombin III deficiency, and rarely factor V Leiden mutations, can predispose to renal arterial thrombosis and infarction in addition to their association with renal vein thrombosis. Hypovolemia, polycythemia, and the use of oral contraceptive agents can increase the risk of thrombosis when these underlying disorders are present.

Antiphospholipid antibody syndrome is associated with both arterial and venous thrombotic events and can involve the renal circulation at any level. In patients younger than 50 years, the antiphospholipid syndrome can account for 15% to 20% of all deep venous thromboses and 30% of strokes. It is the most common cause of spontaneous arterial thrombosis. In one report of 16 cases of renal involvement with this syndrome, 15 of 16 subjects had either arterial or venous thrombosis, 10 had intrarenal microangiopathy, one had suprarenal aortic occlusion, and one had main renal artery thrombosis.¹² Concomitant thromboses in the mesenteric and cerebral circulation have been reported.¹³

Renal Artery Embolism

The kidneys are frequently the target for emboli from thrombus originating in the heart. In one series, 1.4% of the general population had renal artery embolism at autopsy, of which only 2 of 205 cases (1%) were diagnosed clinically.¹⁴ The prevalences of left and right renal emboli are equal, and 12% of cases are bilateral.¹⁵ Atrial fibrillation, cardiac thrombus after myocardial infarction, atrial myxoma or other cardiac tumors, endocarditis, paradoxical emboli, and aortic thrombus represent most of the conditions associated with renal embolism. Atrial fibrillation is

Causes of Renal Infarction
Thrombosis: spontaneous Atherosclerotic disease of aorta and renal artery Fibromuscular dysplasia of renal artery Aneurysms of aorta or renal artery Dissection of aorta or renal artery Marfan syndrome Ehlers-Danlos syndrome Vasculitis involving renal artery Polyarteritis nodosa Takayasu's arteritis Kawasaki disease Thromboangiitis obliterans Other necrotizing vasculitides Inflammatory disease of the aorta or renal artery Syphilis Tuberculosis Mycoses Hypercoagulable states Nephrotic syndrome Antiphospholipid syndrome Antithrombin III deficiency Homocystinuria Thrombotic microangiopathies Hemolytic-uremic syndrome Thrombotic thrombocytopenic purpura Antiphospholipid syndrome Malignant hypertension Scleroderma Sickle cell nephropathy Polycythemia vera Postpartum hemolytic-uremic syndrome Hyperacute vascular allograft rejection
Thrombosis: induced Traumatic Following endovascular intervention Post renal transplantation
Embolism Cardiac source Atrial fibrillation or other arrhythmias Native and prosthetic valvular heart disease Infective endocarditis Marantic endocarditis Myocardial infarction with mural thrombi Left atrial myxoma or other tumor Noncardiac sources Atheromatous embolic disease Paradoxical emboli Fat emboli Tumor emboli Therapeutic renal embolization Segmental renal infarction of childhood Cisplatin and gemcitabine Sickle cell disease or sickle cell trait

Figure 64.7 Causes of renal infarction.

the most common cause, with a rate of embolism four times higher than that of the general population; the highest risk is during the first year after the diagnosis of atrial fibrillation, when anticoagulation is subtherapeutic. When echocardiography is undertaken, cardiac thrombus is only rarely detected. Other causes of renal emboli include fiber or foam related to cardiac bypass procedures, calcium from valve annuli, and even "bullet emboli" in the setting of trauma. Aortic endovascular stenting has been associated with a 10% incidence of new renal infarcts, presumably of embolic etiology.¹⁶

Paradoxical renal artery embolism may occur in patients with right-to-left cardiac shunts. The most common cardiac shunt is

due to atrial septal defects, which are present in up to 9% to 35% of the general population. The diagnosis of paradoxical embolism requires clinical, angiographic, or pathologic evidence of systemic embolism and the presence of venous thrombus along with an abnormal communication between the right and left circulations and a favorable pressure gradient (typically diagnosed by “bubble” echocardiography) for the passage of clot from the right to the left side of the heart.

The clinical presentations of renal artery embolism mirror those of renal infarction (Fig. 64.8).¹⁵ Pain is present in more than 90% of cases confirmed by radiologic imaging techniques. It is unclear from the literature how many go undiagnosed because of lack of clinical symptoms. There is a 30-day mortality rate of 10% to 13% among patients experiencing renal embolism in the setting of atrial fibrillation.¹⁷ Up to 40% of cases have at least transient reduction in renal function.

Whereas angiography is the gold standard for diagnosis of renal artery embolism, nuclear isotope scanning is also very sensitive (97%). Contrast-enhanced CT detects 80% of renal embolic events.¹⁵ In other reports, CT or CTA has a sensitivity nearly matching that of renal angiography.

Aortic and Renal Artery Dissection

Aortic dissection can involve the origin of either renal artery, with the false lumen occluding the vessel and impairing renal perfusion. In this setting, the predictors of renal salvage are the same as those for occlusion due to atherosclerotic renal artery stenosis and include preserved renal size, collateral circulation permitting renal viability, and blush on imaging studies. In one report, despite renal atrophy, aortic stent graft placement allowed renal reperfusion and restoration of renal size and function.¹⁸ Aortic dissection occurs most commonly in association with atheromatous aneurysmal vascular disease of the thoracic aorta, but it can occur in collagen disorders, such as Ehlers-Danlos type IV or Marfan syndrome, and with arteritis, such as Takayasu disease.

Dissection of the renal artery can occur after percutaneous renal angioplasty or stenting (Fig. 64.9), spontaneously with atherosclerotic renovascular disease (ASRD) or fibromuscular dysplasia of the renal artery, or as a complication of renal artery aneurysms. Risk factors for dissection include age, hypertension, connective tissue disorders, pregnancy, bicuspid aortic valve, and coarctation of the aorta. A high index of suspicion and rapid imaging are critical to improve chances of patient and renal survival. Although MRA is nearly 100% sensitive for diagnosis of aortic dissection, CTA has a sensitivity of 93% and is more readily available, has a more rapid turnaround time, is less dependent on patient factors, and is usually the imaging modality of choice.

Middle Aortic Syndrome

A rare entity, middle aortic syndrome is a diffuse narrowing of the aorta, considered a form of coarctation, causing renovascular hypertension (Fig. 64.10). The cause is unknown, but associations with fibromuscular dysplasia, congenital anomalies, neurofibromatosis, Williams syndrome, and Takayasu arteritis have been reported. It can present as aortic thrombosis involving the renal arteries. Repair of middle aortic syndrome before thrombosis is the goal, with angioplasty, surgical repair or autotransplantation of ischemic organs.

Thromboembolic Complication of Endovascular Interventions

Renal artery thrombosis, dissection, laceration, or embolism can occur secondary to vascular interventions, especially those

involving placement of endovascular stents.¹⁹ Occlusion of the vessel within the stent can occur many months to years after stent placement, particularly when in-stent restenosis is present. During the past decade, endovascular aortic stents have been used to treat infrarenal abdominal aortic aneurysms. When the stent crosses the orifice of the renal artery, renal perfusion is impaired, and there is a significant risk for renal artery thrombosis.²⁰ Renal artery stent placement may cause intimal

Figure 64.10 Middle aortic syndrome. Angiogram showing typical smooth narrowing of the aorta. There is bilateral stenosis of paired renal arteries. (From reference 21.)

dissection and thrombosis of the renal artery and even aortic dissection. Stent fracture or kinking can be associated with thrombosis of the lumen. Figure 64.11 demonstrates compression of a proximal renal artery stent with associated thrombotic occlusion of the vessel. Careful studies using filters to capture embolic material confirm that renal artery angioplasty with stenting of atherosclerotic renal arteries releases thousands of particles of various sizes in 70% to 100% of cases.²² Preprocedure treatment with antiplatelet agents and intraprocedural use of embolic protection devices during renal stent implantation are under investigation as a means of reducing the frequency of this underdiagnosed cause of renal infarction.^{23,24}

Renal Artery Aneurysms

Renal artery aneurysms are rare and associated most commonly with atheromatous, fibromuscular, and vasculitic disease (Fig. 64.12). They are manifested clinically as renovascular hypertension, which is the presenting feature in 55% to 75% of cases. Thrombosis within an aneurysm can lead to distal thrombotic emboli and renal infarcts. Aneurysms with diameters of more than 1.5 cm have a higher risk of rupture. Elective repair of large renal aneurysms should be considered in women of childbearing age because of the risk of rupture during the third trimester of pregnancy and in patients with renovascular hypertension. Other complications of renal artery aneurysms include vessel dissection and arteriovenous fistula formation.

Rare Causes of Renal Infarction

Rare causes of renal infarction include autoimmune diseases, such as Behçet's syndrome, systemic lupus, and other autoimmune diseases; Henoch-Schönlein purpura (HSP); chronic Chagas' disease; and drug abuse, such as intravenous injection or nasal insufflation of cocaine or even smoking marijuana. The exact mechanism involved in the pathogenesis of renal infarction in some of these conditions is unclear.

Treatment of Acute Renal Vascular Catastrophe

In the setting of renal infarction, a search for the cause of the renal vascular compromise should be undertaken to determine whether it is embolic or thrombotic. Treatment of the infarction itself is usually conservative and includes pain control and treatment of sometimes labile hypertension. If renal artery occlusion is due to thrombosis associated with hypercoagulable state or embolism from a central source, systemic anticoagulation is indicated. Salvage of the kidney by acute thrombolytic therapy

Figure 64.11 Thrombosis of renal artery complicating renal artery stenting. Right and left renal artery stents note the left renal stent (arrow) is triangular shaped indicating crimping of the proximal portion, which in this case, was associated with thrombosis of the renal artery seen here as no contrast entering the vessel. The right renal stent is patent.

Figure 64.12 Renal artery aneurysm. Angiogram showing large renal artery aneurysm. The aneurysm is patent but is a risk factor for renal artery thrombosis.

has also been attempted with limited success. There is no evidence that thrombolytic therapy can limit infarct size if it is administered in the acute setting.

When embolism from a central source results in renal infarction or renal artery occlusion, a search for the source should include evaluation for atrial fibrillation, cardiac mural or atrial thrombus and mass, and valvular lesions. Except in the situation of septic emboli, anticoagulation is indicated to prevent recurrent embolic events.

Traumatic renal vascular occlusion leads to renal infarction within 3 to 6 hours. Attempts at renal salvage under these circumstances are often unsuccessful unless the diagnosis is made immediately on presentation of the patient and emergent renal revascularization surgery is feasible clinically.

Thrombosis of atherosclerotic renal arteries, because of prior collateral development in most cases, often results in marked

ischemia but not infarction of the kidney and allows consideration of optimal surgical and sometimes percutaneous endovascular revascularization to restore renal function.

ATHEROEMBOLIC RENAL DISEASE

Atheroembolic renal disease is common and may account for up to 10% of unexplained renal failure in the elderly. It most commonly occurs after arterial manipulation in arteriography, vascular surgery, angioplasty, and stent placement. In patients with extensive atherosclerosis with unstable plaques, spontaneous atheroemboli may occur, especially after the administration of oral or intravenous anticoagulants or thrombolytic agents. The incidence of atheroembolic disease after vascular interventions is unclear, but recent data suggest that it is common.²⁵ A study evaluated the frequency of renal perfusion defects in patients after endovascular stent repair of abdominal aortic aneurysms; 18% of the cases had identifiable renal perfusion defects, and the occurrence of these infarcts was significantly associated with atherosclerotic burden.²⁶ Atheroembolism may therefore be expected to occur in up to 30% of patients with extensive aortic atherosclerosis after endovascular intervention. Ipsilateral renal artery stenosis may be present in up to 80% of patients with renal cholesterol embolization. Conversely, cholesterol emboli were found in the kidneys of 36% of the cases undergoing surgical revascularization.²⁷ Thus, cholesterol embolization may contribute to the loss of renal function in patients with atherosclerotic ischemic renal disease.

Most patients are older than 50 years with generalized atherosclerosis and have a history of recent endovascular procedures or signs or symptoms of atherosclerotic vascular disease, such as claudication, abdominal pain, angina, myocardial infarction, transient ischemic attacks, retinal artery emboli, amaurosis fugax, stroke, abdominal aortic aneurysm, renovascular hypertension, or ischemic renal disease. Many have a history of risk factors for atherosclerosis, including hypertension, hypercholesterolemia, diabetes, and smoking.

Clinical Presentation

Acute or subacute renal insufficiency due to renal microinfarctions developing as long as six months following the atheroembolic insult is the most common presentation leading to the diagnosis of cholesterol embolization. The clinical picture is multisystemic in nature and involves the kidneys in about 75% of patients. At autopsy, renal involvement is observed in 92% to 100%.

If a large shower of atheroemboli causes significant tubular damage, the AKI may have an oliguric phase characterized by a high fractional excretion of sodium. More often, the renal failure is nonoliguric and progressive because of ongoing embolization from a nidus of unstable ulcerative plaque. Some patients have only a moderate impairment in renal function, and others progress to end-stage renal disease (ESRD). Atheroembolic renal disease can also present as a more slowly progressive, often stair-stepping subacute renal insufficiency. Urinalysis findings are nonspecific but may include mild proteinuria, microhematuria, pyuria, and eosinophiluria. Renin release by ischemic zones in areas of embolization can lead to labile hypertension early in the course, sometimes associated with transient marked proteinuria. Fever, often low grade, is characteristic.

Although the kidneys are the organs most commonly involved, extrarenal cholesterol embolization will provide clues for

Figure 64.13 Livedo reticularis. The mottled skin changes associated with peripheral cholesterol embolization may be seen over the legs, buttocks, back, or flank and may be transient.

Figure 64.14 Hollenhorst bodies. Cholesterol embolus of a retinal arteriole (arrow). (Courtesy Richard Mills, University of Washington, Seattle, Washington, USA.)

diagnosis. Cutaneous findings in up to 60% of patients at initial presentation include blue or purple toes, mottled skin or livedo reticularis, petechiae, and purpura or necrotic ulceration in areas of skin embolization, such as the lower back, buttocks, lower abdomen, legs, feet, or digits (Fig. 64.13).

Other organs often involved include spleen (in 55% of cases), pancreas (52%), gastrointestinal tract (31%), liver (17%), and brain (14%). This involvement can result in a number of clinical symptoms, including abdominal or muscle pain, nausea, vomiting, ileus, gastrointestinal bleeding, ischemic bowel, hepatitis, angina, and neurologic deficits. When retinal cholesterol embolization occurs, refractile yellow deposits known as Hollenhorst plaques may be seen at the bifurcation of retinal vessels on fundoscopic examination (Fig. 64.14).

Diagnosis

The diagnosis of atheroembolic renal disease is suspected when subacute renal failure develops after a vascular intervention in the presence of livedo reticularis. Myriad laboratory abnormalities indicative of tissue injury are associated with cholesterol embolization, including elevated sedimentation rate (in 97% of cases), elevated serum amylase (60%), leukocytosis (57%), anemia (46%), hypocomplementemia (25% to 70%), and elevated lactate dehydrogenase and creatine kinase (38% to 60%). Eosinophilia, which may be transient, is seen in up to 57% of patients. The presence of eosinophilia should raise suspicion for atheroembolic renal disease in the appropriate clinical setting. Serum lactate is usually not elevated unless concomitant ischemic bowel is present. Definitive diagnosis is made by biopsy of an involved organ or system. A skin or muscle biopsy in an involved area may preclude the need for renal biopsy. In most circumstances, the diagnosis is made clinically.

Differential Diagnosis

Cholesterol embolization syndrome may mimic vasculitis, occult infection, neoplasm, or thrombotic microangiopathy. Contrast nephropathy with nonoliguric acute tubular necrosis (ATN) may also occur after angiography, angioplasty, or aortic vascular surgical procedures but is often more rapid as opposed to the subacute presentation of atheroemboli. Eosinophilia and eosinophiluria, rash, fever, and renal dysfunction may also be misdiagnosed as acute interstitial nephritis (AIN). Chronic cholesterol embolization syndrome may appear similar to hypertensive nephrosclerosis or ischemic renal disease. In the kidney transplant recipient, renal atheroembolism may mimic acute rejection or chronic allograft nephropathy (CAN).

Pathology and Pathophysiology

If clinical or other pathologic evidence has not secured the diagnosis, renal biopsy may be helpful. Diagnosis is based on the presence of birefringent, biconvex, elongated cholesterol crystals or biconcave clefts within the lumina of small vessels left behind in formalin-fixed tissue (Fig. 64.15). Because of the patchy nature of this disorder, open wedge renal biopsy guided by visualization

Figure 64.15 Cholesterol emboli in kidney biopsy specimen. Biconvex cholesterol clefts with giant cell reaction and recanalization of the lumen of a medium-sized renal vessel. (Periodic acid-Schiff stain.) (Courtesy Dr. R. Horn, Vanderbilt University, Nashville, Tennessee, USA.)

of areas of ischemic infarction of the cortex has a higher likelihood of successful diagnosis than does percutaneous needle biopsy. The pathologist should be alerted by the clinician that cholesterol embolization is in the differential diagnosis before the biopsy specimen is processed. In frozen sections of tissue, the cholesterol material can be identified with polarized light microscopy. The pathologic findings may also include intimal thickening and concentric fibrosis of vessels, giant cell reaction to the cholesterol particles, vascular recanalization, endothelial proliferation, tubulointerstitial fibrosis with both eosinophil and mononuclear cell infiltrates, glomerular ischemia, and even focal segmental glomerulosclerosis (FSGS).²⁸ In the kidney, the most commonly affected vessels are the arcuate and interlobular arterioles, leading to patchy ischemic changes distal to these vessels.

Natural History

The natural history is determined by the extent of organ involvement and the degree of the embolization. In one series of cases, renal function declined rapidly in 29%, with a more slowly progressive course seen in 79%.²⁹ Among the latter group, the decline in renal function was thought to result from a combination of cholesterol embolization and ischemic renal disease. In another series, the peak serum creatinine concentration occurred within 8 weeks after an angiographic procedure.³⁰ Patients may also manifest acute or subacute renal insufficiency followed by partial recovery of renal function. Conversely, the outcome can be dismal, particularly when cerebral embolization occurs or when there is a large unstable atheromatous burden. Some patients with cholesterol embolization may develop ESRD. These patients have a mortality rate of 35% to 40% during 5 years, even when dialysis is offered.³⁰

Treatment

The risk for cholesterol embolization should be considered before angiographic and vascular surgical procedures are undertaken in patients with diffuse, extensive atherosclerotic disease. Because prevention is the most effective management strategy, patients with extensive aortic atherosclerosis should be considered for alternative approaches to cardiac catheterization, such as through the brachial artery. If vascular intervention is performed, signs of embolization should be sought both in the immediate postoperative period and for several months thereafter. When it is feasible, distal embolic protection devices should be used to trap embolic material for removal from the circulation to avoid end-organ damage by embolic debris.³¹

After the diagnosis of cholesterol embolization is established, further endovascular interventions should be avoided. Poor outcomes have been reported in patients with cholesterol emboli who subsequently undergo coronary artery bypass surgery. When clinical factors dictate the need for aortic, renal, or peripheral arterial surgery, optimal timing and surgical approach are critical. Conversely, there is a growing surgical experience with segmental aortic replacement to remove the source of emboli, particularly when atheroembolic disease occurs spontaneously. Transesophageal echocardiography is often used to identify mobile ulcerative plaque in the aorta to guide intervention.

Angiotensin-converting enzyme (ACE) inhibitors are effective in managing the labile hypertension seen early in the course of cholesterol embolization. Corticosteroids have been used with some success in patients with systemic cholesterol embolization and associated inflammatory symptoms.³² There have also been

several reports documenting improvement or stabilization of skin signs of cholesterol embolization after administration of statins,³³ which should be part of the treatment of the generalized atherosclerosis in these patients. Cholesterol embolization has also occurred after treatment with anticoagulants. Although direct causality between anticoagulants and cholesterol embolization has not been established, the proposed mechanism is that anticoagulants prevent thrombus organization over the ulcerative plaques. Therefore, anticoagulation should be avoided in the acute setting of cholesterol embolization unless a strong life-threatening indication for anticoagulation is present.

TRANSPLANT RENAL ARTERY STENOSIS AND THROMBOSIS

Epidemiology

Transplant renal artery stenosis is a common post-transplantation complication occurring most often in the period between 3 months and 2 years after transplantation. The highest reported incidence is 23% in a patient cohort screened angiographically, compared with reported incidences of between 1.3% and 12% when other screening tests are used.³⁴ In many cases, anastomotic stenoses are not hemodynamically significant.³⁴ The use of pediatric kidneys in adult recipients is associated with a higher rate of stenosis because of smaller donor vessel size, leading to greater turbulences and mismatch between donor and recipient vessels. As the transplant population ages, there has been increasing recognition of another subset of patients with pseudo-transplant renal artery stenosis, in which vascular disease proximal to the allograft artery, particularly involving the iliac vessel, results in renal ischemia.

Pathogenesis

The pathophysiologic basis for transplant renal artery stenosis is multifactorial and may include atheromatous disease in the donor artery, intimal scarring and hyperplasia in response to trauma to the vessel during harvesting, and anastomotic stenosis, which is most commonly associated with end-to-end anastomoses and may be related to suture technique. In end-to-side anastomoses, stenosis tends to develop in the postanastomotic site, suggesting that turbulence or other hemodynamic factors play a role. Immunologic causes of transplant renal artery stenosis have also been proposed on the basis of histologic similarities with chronic vascular rejection and association with prior acute rejection. Other proposed pathogenic mechanisms include calcineurin inhibitor (CNI) toxicity and cytomegalovirus (CMV) infection.

Clinical Presentation

Patients typically present with new-onset hypertension or difficult-to-control blood pressure (BP) with or without graft dysfunction occurring 3 to 24 months after transplantation. Patients may also present with AKI. When the stenosis occurs in the iliac artery above the anastomosis of the transplanted renal artery (pseudo-transplant renal artery stenosis), the patient often presents with ipsilateral lower extremity claudication associated with hypertension and worsening renal function in the allograft.³⁵ Systolic bruits over the transplant are not diagnostic because they may represent turbulent flow in the main vessels in the absence of stenosis or biopsy-related arteriovenous fistulas. Risk factors

for the development of renal artery stenosis include male gender, hyperlipidemia, and elevated serum creatinine at discharge from transplantation.

Diagnosis

Renal duplex sonography is the screening test of choice for transplant renal artery stenosis because the vessel is superficial and easy to interrogate. The ratio of velocity in the renal and iliac vessels and the resistive index in the kidney have been shown to predict the hemodynamic response to percutaneous transluminal angioplasty. Phase-contrast MRA has an advantage over arteriography in viewing tortuous renal arteries and may provide information additional to Doppler ultrasound regarding the aorta and iliac vessels. However, with MRA, the surgical clip artifact may obscure the proximal renal artery, and it often cannot resolve peripheral renal vessels. High false-positive rates are associated with sharp anastomotic angles. CTA has the advantage over MRA from an imaging standpoint but requires a large amount of contrast material. The gold standard is selective renal angiography of the transplant and iliac artery. In situations in which the risk for contrast-induced nephrotoxicity is high, carbon dioxide angiography can be performed safely.

Treatment

Transplant renal artery stenosis often results in progressive loss of renal function.³⁶ Angioplasty is the preferred initial approach to transplant renal artery stenosis, with initial success rates of up to 75% and patency for follow-up periods of up to 30 months. The average complication rate for angioplasty of the allograft artery is 10%. It is often unsuccessful when there is arterial kinking and is associated with a high complication rate in this setting. The reported rates of late restenosis are between 10% and 33%, necessitating repeated procedures. Although stents are not usually required to treat stenoses within the transplant artery or at the anastomosis, they have been used successfully and are needed routinely to treat the pseudo-transplant renal artery stenosis due to iliac atherosclerotic occlusive disease proximal to the takeoff of the transplant artery.³⁷

Surgical revascularization is reserved for patients in whom angioplasty or stenting has been unsuccessful or complicated. Surgical renal revascularization is difficult and is associated with significant mortality in the transplantation setting. Extensive fibrosis develops around the allograft and often involves the renal vessels, making surgical access risky. Complications include graft loss (in 15% to 30% of cases), ureteral injury (14%), and death (5%).

RENAL VEIN THROMBOSIS

Renal vein thrombosis (RVT) is rare and primarily observed in children with severe dehydration (with an incidence in neonates of 0.26% to 0.7%) or in adults with nephrotic syndrome, renal tumors, or hypercoagulable states and after surgery or trauma to the renal vessels.³⁸ When it occurs in adults, the diagnosis is often never considered. Thrombosis of the longer left (7.5 cm) renal vein may also involve the ureteric, gonadal, adrenal, and phrenic branches that drain into the left vein, whereas on the right side, the adrenal and gonadal veins drain directly into the inferior vena cava. The renal veins also communicate with perirenal veins outside of Gerota's fascia as part of the retroperitoneal collateral venous network: tributaries of the portal system, lumbar, azygos,

and hemiazygos. Because of this network of venous complexes, occlusion of the left renal vein results in enlargement of the systemic collateral vessels and provides some protection against infarction.

Acute Versus Chronic Renal Vein Thrombosis

Experimentally, acute RVT is associated with immediate enlargement of the kidney with marked increase in renal vein pressure, leading to a marked decrease in renal arterial flow. Complications include hemorrhagic infarction, kidney rupture, and retroperitoneal hemorrhage. In the dog, the kidney enlarges during the course of 1 week, then proceeds to atrophy as a result of progressive fibrosis. In contrast, slow, progressive (“chronic”) thrombosis may allow collateral formation, resulting in minimal symptoms.

Clinical Presentation

Acute RVT is usually symptomatic and associated with loin, testicular, or flank pain; low-grade fever; and in the setting of a single kidney or renal transplant, symptoms of renal failure. Nausea and vomiting often accompany acute RVT, and symptoms might be confused with acute pyelonephritis. Leukocytosis can accompany acute thrombosis. Clinical signs include renal enlargement, which in infants is manifested as a palpable abdominal mass. Hematuria is nearly universal and most often is microscopic. The high venous pressures result in a marked increase in proteinuria. Urinalysis sometimes reveals evidence of proximal tubule dysfunction, such as glycosuria. Oliguric renal failure occurs when RVT results in renal infarction of both kidneys or in subjects with a single kidney. In some cases, RVT is diagnosed only after the patient develops an acute pulmonary embolus and the source of the embolus is investigated or with worsening of renal function in the setting of proteinuric chronic kidney disease (CKD).

Chronic RVT may be asymptomatic and is associated with extensive venous collaterals and minimal impairment of renal function and structure. Often, however, microhematuria, increase in proteinuria, and evidence of either reduced GFR or tubular dysfunction are present, particularly when indices of differential renal function are sought, such as with nuclear studies.

When RVT causes renal infarction, the distribution of the hypoperfused region tends to be medullary or subcortical. The renal impairment tends to be patchy and subtotal. These patients can develop severe hypertension acutely. The swollen kidney can rupture the capsule and result in massive retroperitoneal hemorrhage.

Etiology

The causes of renal vein thrombosis are listed in [Figure 64.16](#).

Neonatal Renal Vein Thrombosis

RVT occurs in neonates in situations of dehydration and thrombophilia. There is a greater predilection for development of RVT in male infants, with 67% of the reported cases occurring in boys.³⁹ Most cases are unilateral, with the left renal vein more commonly affected. Complications of neonatal RVT may include adrenal hemorrhage, renal atrophy, renal insufficiency, and hypertension. In neonates, the diagnosis is made by Doppler study of the renal veins. Fibrinolytic therapy may be associated with bleeding complications, including adrenal hemorrhage, and

is usually not successful in restoring renal function unless it is undertaken within 24 hours of the thrombotic event.⁴⁰

Nephrotic Syndrome

Patients with nephrotic syndrome have increased risk of venous thromboembolism; deep venous thrombosis is most commonly diagnosed (see Chapter 15).⁴¹ The prevalence of RVT in nephrotic syndrome is unclear because it is largely undiagnosed; studies report frequencies between 5% and 62%.³⁸ Numerous abnormalities promoting a prothrombotic state occur secondary to heavy proteinuria. Interestingly, RVT appears more common in membranous nephropathy (MN) and lupus nephritis (LN), but RVT can complicate any cause of proteinuric renal disease. In this setting, RVT can lead to an increase in baseline proteinuria and present with AKI superimposed on chronic renal insufficiency.

After Renal Transplantation

RVT after transplantation is rare and occurs in less than 0.1% of transplants, usually within the first week after transplantation. It usually leads to graft infarction. Causes include compression of the renal vein, volume depletion, acute rejection, and hemostatic and hypercoagulable states. Factor V Leiden mutation, which occurs in 2% to 5% of the population, is a risk factor for transplant RVT and should be sought when it occurs. Another syndrome known as sticky platelet syndrome can result in post-transplant RVT. There are some data supporting the protective effects of low-dose aspirin in this population. Immunosuppression with cyclosporine and OKT3 may increase the risk of RVT. Unlike the native kidney, the transplant has only a single renal venous outflow, so the consequences of acute RVT are dire, often leading to loss or rupture of the allograft. Renal salvage is possible with early diagnosis and surgical exploration and thrombectomy.⁴²

Pregnancy

Pregnancy and the postpartum state are hypercoagulable states. There have been reports of spontaneous RVT in the postpartum period associated with renal infarction. RVT complicating pregnancy should be suspected when clinical clues, such as flank pain and hematuria, are present.

Malignant Disease

Malignant disease accounts for the greatest number of cases of RVT.⁴³ RVT can result from invasion of tumor of renal origin into the renal vein. About half of renal cell carcinomas are associated with RVT at autopsy. In addition, neoplasia originating in the renal vein or inferior vena cava, such as leiomyosarcoma or cavernous hemangioma, can cause RVT. Extrinsic compression of the renal vein by a tumor or retroperitoneal fibrosis may also cause this syndrome.

Diagnosis

Diagnosis of RVT requires imaging. Conventional ultrasound may demonstrate alterations in size and echogenicity. Renal duplex sonography may show increases in resistive indices, and ultrasound can directly visualize the filling defect, but this may depend on the angle of the vein, the body habitus of the patient, and the operator's experience. In neonates, renal Doppler ultrasound is the diagnostic study of choice. In adults, both CT and magnetic resonance (MR) venography have much greater sensitivity than renal vein duplex studies. CT venography requires a

Figure 64.17 Computed tomography (CT) venogram demonstrating left renal vein thrombosis (arrow). (Courtesy Dr. S. Rankin, Guy's Hospital, London, United Kingdom.)

significant contrast load, making MR venography preferable in patients with allergy to contrast agents or those at risk for contrast-associated nephrotoxicity. Figure 64.17 is a CT venogram demonstrating unilateral RVT.

Treatment

Treatment is controversial and depends on the setting, acuteness, and renal consequences. If there is no contraindication, most patients are treated with systemic anticoagulation acutely. In adults with acute RVT that is compromising renal function, catheter-directed thrombolytic therapy with urokinase or tissue plasminogen activator with or without percutaneous mechanical thrombectomy can be successful in regaining patency of the vessel and restoring renal function.⁴⁴ There are reports of successful thrombolytic therapy in pregnancy-associated RVT. The long-term benefit of this approach is unclear, and it is less successful when the thrombotic process begins in the small intrarenal venules rather than in the major veins, as is often the case when primary renal disease or a hypercoagulable state initiates the process. In neonatal RVT, which often results in renal non-function, thrombolytic therapy and anticoagulation have been used with variable results. In two recent reports of neonatal RVT, supportive care was recommended for unilateral RVT without extension into the inferior vena cava, whereas thrombolytics were used for bilateral cases with impending renal failure.

Surgical interventions include nephrectomy, thrombectomy, and retroperitoneal surgery for non-renal-associated abnormalities, such as tumor, retroperitoneal fibrosis, aortic aneurysm, and acute pancreatitis. Surgery tends to be reserved for situations in which the RVT results in hemorrhage from renal capsular rupture or for long-term consequences of RVT, such as hypertension or infection of a nonfunctioning kidney resulting from previous RVT.

A conservative approach may be favored when left RVT occurs because of the extensive collateral venous supply on that side, ultimately allowing venous drainage and improvement in renal function. Systemic anticoagulation is indicated acutely to prevent extension of thrombus into the inferior vena cava and for prevention of pulmonary emboli. Anticoagulation should be continued indefinitely in patients with persistent hypercoagulable state after RVT. In addition, eventual recanalization of the

venous system can result in delayed improvement in renal function as measured by nuclear medicine studies.

Geriatric Nephrology

Raimund Pichler, Christian Hugo, Richard J. Johnson

Aging is a slow, inflammatory biologic process that affects many organs, of which the kidney is one of the main targets. Aging is associated with a decline in renal function coincident with a progressive loss of nephrons, with glomerular and tubulointerstitial scarring. These changes begin in the fourth decade of life and accelerate between the fifth and sixth decades, resulting in alterations in glomerular and tubular function, systemic hemodynamics, and body homeostasis. Although aging-related changes begin in midlife, this chapter focuses on the management of the older population, defined as older than 65 years.

Aging-associated renal disease may not be inevitable. Some subjects do not show age-related decline in GFR. Hypertension does not increase with aging in non-westernized populations habitually on low-sodium diets. This has led some to hypothesize that aging-associated renal disease may be an active process that is potentially preventable.

AGING-ASSOCIATED DECLINE IN RENAL FUNCTION

Glomerular Filtration Rate

Inulin clearance studies document a progressive fall in glomerular filtration rate (GFR) after the age of 40 years, with a relatively greater decline in men (Fig. 65.1).¹ However, the fall in GFR is not inevitable; in as many as one third of subjects who remain normotensive, there is no decrease in creatinine clearance with age.²

In addition to the decrease in GFR with aging, there may be a reduction in renal “reserve.” Whereas some studies suggest that aging humans show a normal increase in GFR after amino acid infusion, others have shown a marked reduction in increases in renal plasma flow and GFR in response to concurrent infusion of amino acids and dopamine in healthy elderly individuals.^{3,4}

Renal Plasma Flow

Renal plasma flow (RPF) also decreases from a mean of 650 ml/min in the fourth decade to 290 ml/min by the ninth decade, with increasing renal vascular resistance (Fig. 65.2).¹ The fall in RPF with age is greater in men than in women and in those who are hypertensive.⁵ Because RPF decreases relatively more than GFR, filtration fraction (defined as GFR/RPF) increases with age.

The decrease in RPF does not simply reflect a decrease in renal mass. Studies using a xenon washout technique demonstrated that there is a true reduction in renal blood flow when it

is factored for renal mass.⁶ The decrease in renal blood flow especially involves the cortex, and blood flow to the medulla is relatively preserved.

Proteinuria

The prevalence of both microalbuminuria (urinary albumin levels of 30 to 300 mg/day) and albuminuria increases progressively in the U.S. population after the age of 40 years. The increased prevalence is most marked in diabetic and hypertensive subjects but is also observed in patients lacking these risk factors (Fig. 65.3).⁷ The prevalence of microalbuminuria and albuminuria is higher in African Americans, Mexican Americans, and those with elevated serum creatinine.⁷ This is clinically relevant because microalbuminuria is an independent risk factor for cardiovascular disease (such as carotid disease and left ventricular hypertrophy) and cardiovascular mortality.

ASSESSMENT OF RENAL FUNCTION IN THE ELDERLY

Serum creatinine is a less reliable indicator of renal function in the aging population. This is because creatinine generation reflects muscle mass, and muscle mass decreases with aging. Men normally excrete 20 to 25 mg/kg body weight of creatinine in the urine each day, and women excrete 15 to 20 mg/kg body weight of creatinine. However, after the age of 60 years, there is a progressive decrease in urinary creatinine excretion, resulting in excretion rates lower than these ranges (Fig. 65.4).⁸ For example, in one study, serum creatinine did not change between young subjects (mean age of 30 years) and older subjects (mean age of 80 years) despite a reduction in creatinine clearances from 140 ml/min per 1.73 m² at age 30 years to 97 ml/min per 1.73 m² at age 80 years.⁹

There is no consensus on the optimal approach to estimation of GFR in elderly people. Whereas the MDRD (Modification of Diet in Renal Disease) study equation and the Cockcroft-Gault formula for estimating GFR use age in their calculations (see Chapter 3), neither has been validated in a population older than 70 years, and both underestimate true GFR in those older than 65 years with standard techniques such as technetium Tc 99m. Although the MDRD equation may be more accurate than the Cockcroft-Gault formula,^{10,11} serum cystatin C, which is independent of muscle mass, may be superior to both and is an independent risk factor for mortality in the elderly.¹² Renal function was assessed in a community-based survey of the elderly in Finland by

Figure 65.1 Glomerular filtration rate (GFR) decreases with age. GFR (inulin clearance) begins to fall at age 40 years, and the rate of decline is more rapid in men than in women. (Modified from reference 1.)

use of the MDRD equation, Cockcroft-Gault formula, and serum cystatin C; only cystatin C correlated with albuminuria.¹³

PREVALENCE OF CHRONIC KIDNEY DISEASE IN THE ELDERLY

According to the National Health and Nutrition Examination Survey (NHANES; 1999-2004), nearly 45% of elderly subjects

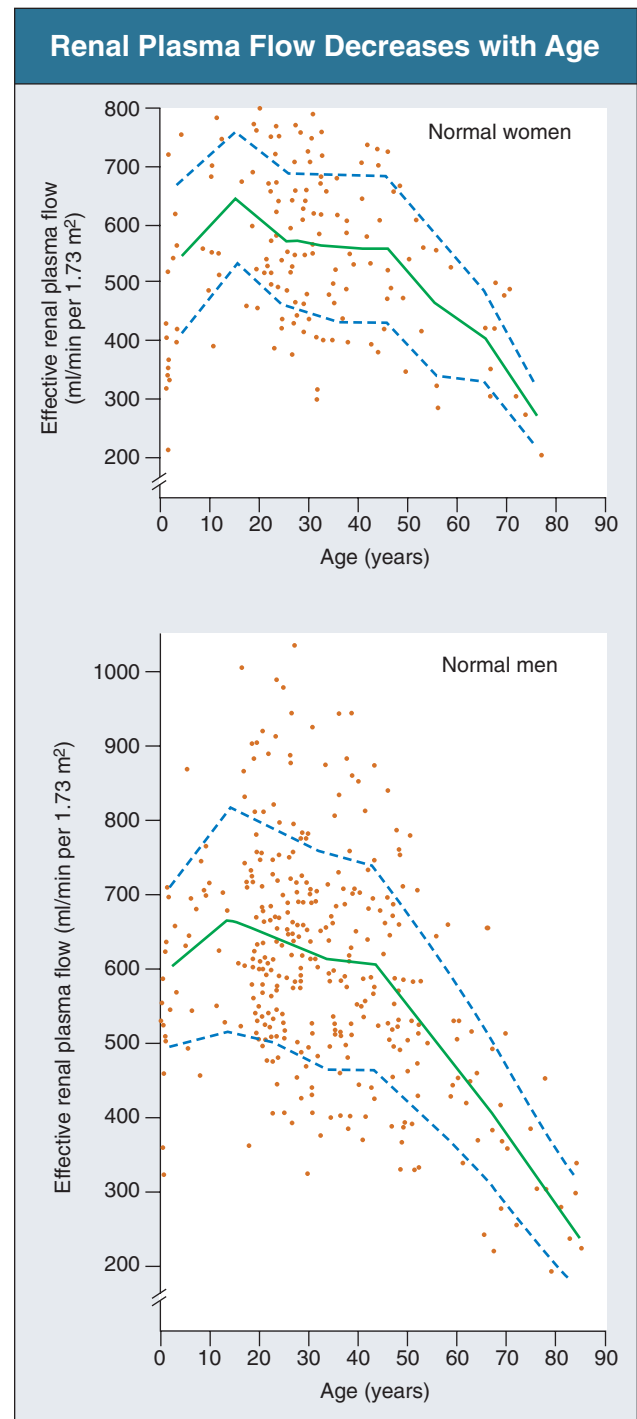

Figure 65.2 Renal plasma flow (RPF) decreases with age. RPF (*p*-aminohippurate clearance) begins to fall rapidly after the age of 50 years, and the rate of decline is more rapid in men than in women. (Modified from reference 1.)

have chronic kidney disease (CKD, stages 1 to 4) in the United States compared with only 8% of the overall adult population (Fig. 65.5).¹⁴ Elderly subjects older than 70 years account for half of people with CKD as defined by the KDOQI classification using the MDRD equation (see Fig. 65.5).¹⁴ Furthermore, the prevalence of CKD in the elderly U.S. population appears to have increased by 10% compared with a decade ago.¹⁴

CKD is associated with an overall increase in all-cause cardiovascular mortality.¹⁵ Nevertheless, reductions of eGFR to 50

Figure 65.3 Increased proteinuria with aging. **A**, Microalbuminuria increases with age, with the greatest prevalence in diabetes, followed by hypertension and then the absence of either condition. **B**, Albuminuria increases with age, and the prevalence is greater in men than in women. (Modified from reference 7.)

to 59 ml/min per 1.73 m² do not increase mortality risk among patients age 65 years or older compared with patients with eGFR of more than 60 ml/min (Fig. 65.6).^{16,17} These observations have led to the debate whether the decrease in GFR that occurs with aging should really be considered unhealthy and whether the term CKD should be applied to subjects with aging-associated decline in renal function.¹⁸

Risk Factors for Aging-Related Chronic Kidney Disease

The variability in the severity of aging-related renal disease in humans and experimental animals has suggested that there may be specific risk factors for its development. In experimental models, aging-related histologic changes vary according to the genetic strain, gender, body mass index, and diet. In general, aging-associated renal injury is worse in men, in obesity, or in the setting of endothelial dysfunction, and aging changes can be retarded with protein or calorie restriction or blockade of the renin-angiotensin system (RAS).¹⁹

Pathology

The human kidney reaches a maximum size of about 400 g (corresponding to 12 cm in length) in the fourth decade of life. After

Figure 65.4 Urinary creatinine excretion (factored for body weight) decreases with age. (Modified from reference 8.)

this, renal mass decreases at a rate of about 10% per decade, with a tendency for decrease to be greater in men than in women. Macroscopically, the kidneys develop an appearance of granularity and pitting of the external surface. There is progressive cortical thinning and loss in the number of functional nephrons (Fig. 65.7).

Glomerular number decreases from about 1 million per kidney to 600,000 or less by the eighth decade. Pathologic glomerular changes include glomerular hypertrophy, basement membrane thickening, and progressive development of focal segmental or, rarely, global glomerulosclerosis. At birth, less than 5% of glomeruli show glomerulosclerosis, but this increases to 10% to 30% of glomeruli by the eighth decade (Fig. 65.8).²⁰ It has been suggested that glomerulosclerosis should be considered “pathologic” if the percentage of globally sclerosed glomeruli exceeds (age/2) – 10.²¹ The glomerulosclerosis is associated with mesangial matrix expansion and a progressive loss of capillary loops. Periglomerular fibrosis is often prominent, and there may be “atubular glomeruli,” in which the exit from Bowman’s capsule to the proximal tubular lumen is blocked by fibrosis.

Tubulointerstitial injury is greatest in the outer medulla and medullary rays, with tubular dilation and atrophy, mononuclear cell infiltration, and interstitial fibrosis. Distal tubules and collecting ducts may develop small diverticula; it has been suggested that these diverticula harbor bacteria predisposing to recurrent pyelonephritis.²

Arteriolar hyalinosis is common with aging but is observed almost exclusively in hypertensive individuals.² There is also increased tortuosity of the arcuate and interlobar vessels. Some afferent arterioles, particularly of juxtamedullary glomeruli, also develop vascular shunts to the efferent arterioles, thereby bypassing glomeruli, leading to “aglomerular arterioles.”²² Studies in rats have also demonstrated focal losses of glomerular capillary loops and peritubular capillaries consistent with a state of impaired angiogenesis.²³

Pathogenesis of Aging-Associated Chronic Kidney Disease

A variety of mechanisms have been proposed for aging-related renal changes (Fig. 65.9).

One mechanism may involve *senescence*, in which there is telomere shortening of chromosomal DNA, loss of mitochondria,

Figure 65.5 Prevalence of chronic kidney disease (CKD) stages by age group in NHANES 1988–1994 and 1999–2004. ^aThere were no cases in 1988–1994. (Modified from reference 14.)

Figure 65.6 Adjusted hazard for death associated with an eGFR of 50 to 59 ml/min per 1.73 m^2 . (Modified from reference 16.)

Figure 65.7 Glomerulosclerosis and tubulointerstitial fibrosis in an aging rat. Similar changes, consisting of focal segmental glomerulosclerosis, tubular atrophy, and interstitial fibrosis, occur in humans. (Trichrome stain; original magnification $\times 400$.)

and accelerated apoptosis. Increased numbers of apoptotic tubular and interstitial cells have been shown in the aging rat.²⁴ This process may involve oxidative stress.²⁵

Aging-associated renal disease may also be mediated by activation of the *renin-angiotensin system* (RAS). Although aging is associated with extracellular volume expansion and a reduction in plasma renin activity, there is evidence in aging rats that renal angiotensin II (Ang II) levels are elevated. Treatment of rats with angiotensin-converting enzyme (ACE) inhibitors reduces aging-associated oxidative stress and preserves mitochondria in renal proximal tubules in association with upregulation of cellular antioxidant enzymes.^{26,27} Rats treated with ACE inhibitors shortly after birth also develop less glomerulosclerosis and tubulointerstitial fibrosis with aging.²⁸ The renoprotective mechanisms may be both hemodynamic (decreasing glomerular hydrostatic pressure and increasing renal blood flow) and nonhemodynamic

Figure 65.8 Glomerulosclerosis increases with aging. (Modified from reference 20.)

Proposed Mechanisms for Aging-Associated Renal Disease

Oxidative stress
Senescence (with telomere shortening and loss of mitochondria)
Glomerular hypertension and hyperfiltration
Intrarenal activation of the renin angiotensin system
Endothelial dysfunction (loss of nitric oxide)
Renal ischemia
Renal TGF- β expression
Accumulation of advanced glycation end products (AGEs)
Chronic effects of uric acid

Figure 65.9 Proposed mechanisms for aging-associated renal disease. TGF- β , transforming growth factor β .

(direct effect to block Ang II–mediated oxidative stress and cytokine [transforming growth factor β] production).²⁹ In addition, lifelong blockade of the RAS in rats results in less left ventricular hypertrophy and myocardial fibrosis, improvement in learning capacity, increased sexual activity, and decreased liver fibrosis.^{26,29–31} Targeted disruption of the gene encoding for the AT_{1A} receptor also results in marked prolongation of life span in mice despite unchanged renal function or histology after 24 months.³¹ The longevity in these mice was associated with a decrease of cardiac and vascular injury possibly through attenuation of oxidative stress and overexpression of prosurvival genes (also in the kidney).

A loss of nephrons results in *hyperfiltration* with increased glomerular hydrostatic pressure and glomerular hypertrophy, which are known risk factors for glomerular scarring.³² However, studies in aging rats have shown that the initiation of renal damage with aging may occur independently of glomerular hypertension. Depending on the strain, glomerular hydrostatic pressures may be either elevated or normal with aging.¹⁹ It is thus likely that glomerular hypertension, when it occurs with a decrease in nephron mass, is a contributor to rather than an initiator of the aging-associated decline in renal function.

With aging, there is dilation and stiffening of elastic arteries³³ that result in higher pulse wave velocity with increased pressure transmission to the microvasculature.³⁴ Measures of large artery stiffness are closely related to markers of renal microvascular injury, including albuminuria.³⁵ Aging-associated intimal hyperplasia of the interlobular arteries and disease of the afferent arteriole may also alter renal autoregulation, resulting in injury to the glomeruli.³⁶ Higher systemic pulse pressure, seen in aging individuals, has been associated with an accelerated decline in kidney function.³⁷

Endothelial function also declines with aging, and this is greater in men than in women. The endothelial dysfunction is associated with a progressive reduction in nitric oxide production by endothelial cells and is reflected clinically by a reduction in brachial artery reactivity.³⁸ The loss of normal endothelial vasodilatory substances may account for the increased renal vasoconstrictive response observed in aging rats to agents such as Ang II and endothelin 1 and may also contribute to the development of renal microvascular disease. Endothelial dysfunction can also inhibit renal angiogenesis, resulting in progressive capillary loss and ischemia. Indeed, mice lacking endothelial nitric oxide

synthase show a marked acceleration of aging-associated renal disease.

Aging is also associated with more pronounced *renal hypoxia*. Blood oxygenation level–dependent magnetic resonance imaging studies have shown that ambient Po₂ is about 20 mm Hg lower in both the renal cortex and the medulla in otherwise healthy aged individuals compared with young subjects.³⁹ The reduced ability of the aged kidney to generate nitric oxide and vasodilatory prostaglandins may also contribute to renal hypoxia.^{40,41}

Advanced glycation end products (AGEs), although typically associated with diabetes, are also present in the diet and can accumulate in aging. The content of AGEs in the diet correlates with serum AGE levels, oxidant stress, organ dysfunction, and life span.⁴² Calorie restriction may extend life span in animal models in part by reducing AGE levels.^{42,43} Chronic administration of aminoguanidine (an inhibitor of AGE synthesis) also reduces glomerulosclerosis in the aging rat.

FLUID AND ELECTROLYTES IN AGING

Sodium Balance and Hypertension

Aging is associated with both impaired sodium excretion of a salt load⁴⁴ and defective conservation in the setting of sodium restriction.⁴⁵ Proximal sodium reabsorption (reflected by lithium clearance) is increased in aging, whereas distal sodium reabsorption may be reduced.⁴⁶ Studies in rats suggest that pressure natriuresis is impaired in aging.¹⁹ Because the diet of most individuals in developed countries contains excess sodium (8 to 10 g salt/day), there is a tendency in the elderly population for total body sodium excess.

The relative defect in sodium excretion and increased total body sodium may be a predisposing factor for the development of hypertension. Blood pressure increases with age. After the age of 60 years, most of the population is hypertensive (Fig. 65.10).⁴⁷ Salt sensitivity occurs in more than 85% of the aging population, and sodium restriction will result in a significant fall (>10 mm Hg) in mean arterial pressure.⁴⁸ Populations that ingest low-sodium diets, such as the Yanomamo Indians of southern Venezuela, do not show an increase in blood pressure with age.⁴⁹ Loss of vascular compliance due to collagen deposition in the larger arterial vessels may also contribute to aging-associated hypertension, as may endothelial dysfunction, perhaps mediated by oxidative stress.

Aging-associated renal and vascular changes may explain why correction of secondary forms of hypertension (such as primary aldosteronism, Cushing's syndrome, renovascular hypertension, and hypothyroidism) is less effective at curing hypertension in older patients. In one study, diastolic blood pressure fell to below 90 mm Hg in 24 of 25 subjects younger than 40 years after treatment of the mechanism responsible for the secondary hypertension but in only 38 of 61 subjects older than 40 years.⁵⁰

Osmoregulation and Water Handling

There is impaired water handling with aging. Both concentration and dilution are affected, and nocturia is common. There is a reduced maximal urinary osmolality and thirst response to hyperosmolality, which may predispose to dehydration and hypernatremia. The increase in urine osmolality in response to antidiuretic hormone (vasopressin) is blunted compared with younger subjects. Total body water also decreases with age. Conversely, there is slower excretion of a water load, leading to an increased predisposition to hyponatremia.

Figure 65.10 Prevalence of hypertension based on age, gender, and race. (Modified from reference 47.)

Other Tubular Defects and Electrolyte Problems

Potassium excretion is impaired, probably because of reduction in numbers of functioning tubules. Hyperkalemia occurs more frequently in elderly subjects treated with drugs that interfere with potassium excretion (such as potassium-sparing diuretics). Other factors contributing to the predisposition for hyperkalemia in the elderly include decreased GFR, lower basal levels of aldosterone, and tubulointerstitial scarring impairing the Na^+, K^+ -ATPase transporters. Hypokalemia is also common because of renal or extrarenal losses.

Acid-base disturbances may result from the impaired distal tubular acidification that occurs with aging. Aging subjects do not excrete an acid load as effectively as younger subjects do.

Hypercalcemia occurs in 2% to 3% of institutionalized elderly patients. Causes include malignant tumors, hyperparathyroidism, immobilization, and use of thiazide diuretics. Hypocalcemia is less common and is observed mainly in patients with advanced CKD, chronic malabsorption, and severe malnutrition. Aging is associated with increased parathyroid hormone levels (which correlate inversely with GFR) and a decrease in serum calcitriol and phosphate.⁴⁶

Hypomagnesemia is reported in 7% to 10% of elderly patients admitted to the hospital; most commonly, this is the result of malnutrition, laxatives, or diuretic use. Hypermagnesemia is less common and is found primarily in patients with CKD or who are taking large doses of magnesium-containing antacids. Gout (as well as an elevation in serum uric acid levels) is also more common in the aging population.

ENDOCRINE FUNCTION AND RENAL HORMONES

Erythropoietin (EPO) levels increase with age, probably related to a compensatory response to subclinical blood loss, increased erythrocyte turnover, and increased EPO resistance.⁵¹ Nevertheless, EPO levels are significantly lower in the anemic elderly subject compared with the anemic younger individual, suggesting a blunted response to low hemoglobin.⁵²

Elderly women with GFR below 60 ml/min have lower calcium absorption and lower 1,25-hydroxyvitamin D levels,

probably due to diminished conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D by the aging kidney.⁵³

The kidney removes about 50% of insulin in the peripheral circulation by filtration and proximal tubular uptake and degradation. The decline of renal function in the elderly leads to a decrease in insulin clearance. This is in part offset by diminished glucose tolerance, which may relate to the increasing frequency of obesity observed in aging individuals.⁵⁴

CLINICAL MANIFESTATIONS

General Considerations

Given the limitations of glomerular and tubular function in elderly people, fluid and electrolyte management needs constant vigilance to minimize morbidity. Fluid and electrolyte homeostasis is easily destabilized by intercurrent challenges that are well tolerated by younger patients. Moderate fluid loss (e.g., episode of diarrhea) and moderate fluid loading (e.g., inappropriate perioperative intravenous fluids) are both poorly tolerated and may lead to hypovolemia and fluid overload, respectively. Overzealous administration of water as 5% dextrose or 0.45% saline may result in hyponatremia. The acid load provoked by ischemic tissue injury or hypoxemia will be more severe in the elderly owing to inadequate renal compensation. Potassium homeostasis is easily altered by inaccurate estimation of intravenous or potassium requirements. The use of nonsteroidal anti-inflammatory drugs (NSAIDs) in the elderly is associated with increased risk for hyponatremia, hyperkalemia, hypertension, and impaired renal function.

Glomerular Diseases

Patterns of glomerular disease seen in elderly people are similar to those seen in the general population, although certain disorders may have an increased prevalence. Diabetic kidney disease is seen with increasing frequency in the aging population; however, older patients almost always have a mixture of different entities, most commonly of hypertensive nephrosclerosis and atherosclerosis. Also seen with increased frequency are membranous nephropathy, Wegener's granulomatosis, membranoprolif-

Figure 65.11 Epidemiology of primary glomerulonephritis by age. (Modified from reference 55.)

erative glomerulonephritis, and amyloidosis (Fig. 65.11).^{18,55} In contrast, certain glomerular disorders are uncommon in elderly people, such as lupus nephritis, minimal change nephropathy, and IgA nephropathy. Only 2% of patients with systemic lupus erythematosus present after the age of 60 years.¹⁸ As a consequence, most positive results of fluorescent antinuclear antibody tests performed in elderly patients are false-positive test results. Other diseases may be less typical in the elderly.

Renovascular and Atheroembolic Disease

There is also an increased frequency of renovascular and atheroembolic disease with aging. The observation of hypertension and elevated serum creatinine, especially in an individual with a history of vascular disease, should prompt a screening test for renovascular disease, such as by magnetic resonance angiography or by renal artery duplex scanning (see Chapter 37).

Acute Kidney Injury

Elderly subjects are at marked increased risk for acute kidney injury in many settings, including after surgery. Mechanisms involved include reduction in functional renal reserve, impaired renal autoregulation, defective fluid homeostasis, and increased susceptibility to drug nephrotoxicity.

Urinary Tract Infections

There is an increased risk for asymptomatic bacteriuria and symptomatic urinary tract infection with aging (see Chapter 51). In men, this may relate to the increased risk for prostatic hypertrophy and urinary calculi with age. Chronic use of indwelling catheters in elderly subjects is also associated with increased bacterial colonization rates; treatment of these urinary tract infections should generally be based on the presence of symptoms or signs (fever, elevated white blood cell count, or dysuria). Exceptions include high-risk subjects, such as those with fre-

quent or recurrent urinary tract infections or structural defects of the urinary tract, patients scheduled to undergo urologic surgery, neutropenic patients, and renal transplant recipients. The treatment of catheter-associated infections is discussed in Chapter 51.

Obstructive Uropathy

Obstructive uropathy (see Chapter 58) is common in elderly men, usually due to benign prostatic hypertrophy, prostate cancer, or urethral stricture. The incidence of obstructive uropathy in women is about one third to one half that in men and is primarily due to malignant neoplasms of the genitourinary tract. Lower urinary tract obstruction should be excluded by measuring the postvoid residual bladder volume, either by a bedside ultrasound bladder scan or by temporary placement of a urethral catheter. Ultrasound is the most appropriate imaging study for diagnosis of upper urinary tract obstruction (see Chapter 58).

Urinary Incontinence

The lower urinary tract also undergoes significant changes with aging. Decreased bladder contractility occurs secondary to weakening and thinning of the detrusor smooth muscle. This leads to a dysfunctional pattern, eventually culminating in involuntary detrusor contractions. Bladder capacity decreases, whereas postvoid residual bladder volume increases by about 50 to 100 mL. Elderly people also have a higher frequency of nocturia, due in part to the decrease in renal concentrating capacity and perhaps also associated with disordered sleep.

Transient urinary incontinence is very common in the elderly with multiple potentially treatable causes, which are best recalled by a mnemonic, DIAPPERS (Fig. 65.12).⁵⁶ In men, the most common cause is overflow incontinence from prostatic obstruction, whereas in women, a prolapsed uterus is frequently the cause. If a reversible cause is not promptly identified, referral to a neurologist (to rule out conditions such as normal-pressure hydrocephalus) or urologist is recommended.

In the absence of an easily reversible cause, nonsurgical therapeutic options for urinary incontinence include behavioral therapy and biofeedback, pelvic floor exercises, pharmacologic therapy (e.g., α -adrenergic antagonists to reduce prostatic hypertrophy), and, if it is unavoidable, long-term catheterization. Surgery may be required for large cystoceles, vaginal vault prolapse, and postprostatectomy stress incontinence.⁵⁶

Incidence and Prevalence of ESRD in the United States by Age

Figure 65.13 Incidence and prevalence of ESRD in the United States by age. Subjects older than 65 years have a higher incidence and prevalence of ESRD; factored for gender and race. (Modified from U.S. Renal Data System [USRDS]: 2005 Annual Data Report. *Am J Kidney Dis* 2006;47[Suppl 1]:S65-S81.)

Hematuria

Malignant neoplasms of the urinary tract are more common in older subjects. Bladder carcinoma is rarely observed before the age of 40 years in men and is even more uncommon in women younger than 40 years; it increases progressively after the fourth decade. Renal cell carcinomas are most commonly observed in the seventh decade. As a consequence, the development of microhematuria or macrohematuria requires thorough urologic evaluation. Other causes of hematuria may need to be considered, including glomerular disease and stone disease, as discussed in Chapter 59.

Nephrotoxicity and Drug Dosing

Elderly subjects are prone to increased nephrotoxicity both as a consequence of decreased renal mass and because they are often administered medicines on the assumption that a normal or nearly normal serum creatinine concentration is consistent with normal renal function. As a result, elderly subjects are commonly prone to nephrotoxicity from NSAIDs, cyclooxygenase 2 inhibitors, aminoglycosides, radiocontrast media, and chemotherapy (e.g., cisplatin).

Drug dosing needs to be carefully adjusted in the aging patient. Certain common drugs frequently need adjustment for renal function; these include aminoglycosides, digoxin, procainamide, tetracycline, and vancomycin. Certain drugs may be commonly associated with the development of hyponatremia; these include thiazides and chlorpropamide. Other drugs commonly prescribed in elderly subjects may rarely be associated with the development of nephrotic syndrome. These include NSAIDs and pamidronate.

End-Stage Renal Disease and Renal Replacement Therapy

Given the normal decrease in GFR with aging, it is not surprising that end-stage renal disease (ESRD) is common in the elderly. Both the incidence and prevalence of ESRD are higher

in older subjects (Fig. 65.13). Indeed, the mean age for a patient to initiate renal replacement therapy is currently 63 years in the United States. Most cases of ESRD in older subjects are due to either diabetes or hypertension.

Despite the frequency of CKD among elderly patients, ESRD is far less common than cardiovascular morbidity or mortality.⁵⁷ Older patients with CKD stage 3 are more likely to die and less likely to reach ESRD than are their younger counterparts.⁵⁸

The clinical presentation of ESRD in the elderly may also differ from that in younger patients. Patients may present with uremic symptoms (anorexia, nausea, and pruritus), with only modest elevations in serum creatinine, and such uremic manifestations may be attributed to the “aging process” or other comorbidities.

Occasional subjects may present with unexplained dementia or change in personality or behavior, unexplained exacerbation of congestive heart failure, or simply a change in sense of well-being. The decision to offer renal replacement therapy is no longer based on the age of the individual. Patients often do very well with either hemodialysis or peritoneal dialysis unless there are comorbid conditions such as cardiovascular disease. As with younger subjects, vascular access remains the Achilles heel of hemodialysis. Even in this population, the survival of arteriovenous fistulas is significantly greater than that of arteriovenous grafts. Some surgeons justify use of synthetic grafts in the elderly on the grounds that their blood vessels are fragile and significantly atherosclerotic. However, successful use of an arteriovenous fistula has results similar to those in younger people, with prolonged patencies and low incidence of infections and thromboses.

Transplantation should be considered in the management of elderly patients with ESRD because studies have clearly shown that the elderly recipient benefits from renal transplantation by a significant reduction in mortality (41%) compared with wait-listed ESRD patients.⁵⁹ This survival benefit is most striking for patients with ESRD caused by diabetes or hypertension,⁵⁹ but it becomes less apparent the longer the patient waits before transplantation.⁶⁰ The proportion of patients with ESRD who are older than 65 years and on the transplant waiting list has tripled

in the past 10 years in the United States and currently exceeds 12%.⁶⁰

Elderly subjects were thought to have a lower rate of graft rejection than younger patients. However, because they have a higher rate of death with functioning grafts, overall graft survival is similar to that in younger subjects.⁶⁰ On the basis of these studies, it has been argued that lower doses of immunosuppression are sufficient in elderly renal transplant recipients.⁶¹ However, the Eurotransplant Senior Program allocating kidneys from donors 65 years or older to recipients 65 years or older regardless of HLA matching found 5% to 10% increased rejection rates in this “old to old” group compared with two better HLA-matched groups, the “old to any” and the “any to old,” within the Eurotransplant Kidney Allocation System.⁶² In a subanalysis of the ELITE-Symphony study, a large prospective, randomized trial comparing immunosuppressive regimens in renal transplant patients,⁶³ equal rates of rejection in elderly (≥ 60 years) versus younger (< 60 years) recipients were demonstrated. Furthermore, this subanalysis suggested that older recipients who receive a marginal kidney from an older or expanded criteria donor may fare worse than younger recipients, with an increased likelihood of death, delayed graft function, graft loss, treatment failure, and reduced graft function. The use of a standard criteria donor kidney may therefore be especially important for elderly patient survival within the first year after renal transplantation. However, in the current dilemma of global organ shortage, in which expanded criteria donor kidneys represent about 17% of deceased donor kidney transplants in the United States,⁶⁴ this approach raises an ethical dilemma about fair kidney allocation.

Pathophysiology and Etiology of Acute Kidney Injury

J. Ashley Jefferson, Joshua M. Thurman, Robert W. Schrier

DEFINITION

Acute kidney injury (AKI) is a clinical syndrome denoted by an abrupt decline in glomerular filtration rate (GFR) sufficient to decrease the elimination of nitrogenous waste products (urea and creatinine) and other uremic toxins. This has traditionally been referred to as acute renal failure (ARF), but in recent years, an effort has been made to implement the term AKI instead of ARF and to develop a standardized definition of AKI. One proposed definition of AKI, for example, is a decline in kidney function during 48 hours as demonstrated by an increase in serum creatinine of more than 0.3 mg/dl, an increase in serum creatinine of more than 50%, or the development of oliguria.¹ Staging criteria (see Chapter 68) have also been based on the magnitude of the rise in serum creatinine and changes in the volume of urine output during 1 week,¹ and studies have validated that these staging criteria are of prognostic value.

ETIOLOGY OVERVIEW

Although AKI is defined by a reduced GFR, the underlying etiology of the renal impairment is most frequently due to tubular and vascular factors. AKI can be due to a broad range of causes, and the differential diagnosis must be considered in a systematic fashion to avoid missing multiple factors that may be contributing to the condition. The traditional paradigm divides AKI into prerenal, renal, and postrenal causes. Prerenal AKI may be due to hypovolemia or a decreased effective arterial volume. Postrenal obstructive renal failure is usually diagnosed by urinary tract dilation on renal ultrasound or computed tomography scanning. Intrinsic renal causes of AKI should be considered under the different anatomic components of the kidney (vascular supply, glomerular, tubular, and interstitial disease; Fig. 66.1). Major extrarenal artery or venous occlusion must also be considered in the differential diagnosis (see Chapter 64). Similarly, disorders of the small intrarenal vasculature can result in AKI (e.g., vasculitis, thrombotic microangiopathy, malignant hypertension, eclampsia, postpartum states, disseminated intravascular coagulation, scleroderma; see Chapters 24, 28, 36, 42, and 62). All forms of acute glomerulonephritis can present as AKI, as can acute inflammation and space-occupying processes of the renal interstitium (e.g., drug-induced, infectious, and autoimmune disorders; leukemia; lymphoma; sarcoidosis).

In the hospital setting, prerenal uremia and acute tubular necrosis (ATN) account for the majority of AKI cases (Fig. 66.2).² The term *tubular necrosis* is a misnomer because the alterations are not limited to the tubular structures and true cellular necrosis in human ATN is often minimal. However, the term

ATN is commonly employed in the clinical setting. To make things even more confusing, the terms ATN, ARF, and AKI are frequently used interchangeably in the literature. The term ATN should be reserved for cases of AKI in which a renal biopsy (if performed) would show the characteristic changes of tubular cell injury (Fig 66.3) or for patients with findings of tubular injury (such as renal tubular epithelial cells in the urine sediment) in an appropriate clinical setting.

There are also significant geographic differences in the causes of AKI; the spectrum of causes in tropical countries is described in Chapter 67. Obstetric AKI remains more common in emerging countries. There are also different patterns of accidental and deliberate self-poisoning. In Africa, herbal toxins are a common cause of AKI. Severe hemolysis may also occur in malaria; with drugs in association with glucose-6-phosphate dehydrogenase deficiency; and after spider, snake, and insect bites.

PATHOPHYSIOLOGY AND ETIOLOGY OF PRERENAL AZOTEMIA

Impaired renal perfusion with a resultant fall in glomerular capillary filtration pressure is a common cause of AKI. In this setting, tubular function is typically normal, renal reabsorption of sodium and water is increased, and consequently urine chemistries reveal a low urine sodium (<10 mmol/l) and a concentrated urine (urine osmolality >500 mOsm/kg).

A marked reduction in renal perfusion may overwhelm autoregulation and precipitate an acute fall in GFR. With lesser degrees of renal hypoperfusion, glomerular filtration pressures and GFR are maintained by afferent arteriolar vasodilation (mediated by vasodilatory eicosanoids) and efferent arteriolar vasoconstriction (mediated by angiotensin II). In this setting, AKI may be precipitated by agents that impair afferent arteriolar dilation (nonsteroidal anti-inflammatory drugs [NSAIDs]) or efferent vasoconstriction (angiotensin-converting enzyme [ACE] inhibitors and angiotensin receptor blockers [ARBs]).

Prerenal azotemia is commonly secondary to extracellular fluid volume depletion due to gastrointestinal losses (diarrhea, vomiting, prolonged nasogastric drainage), renal losses (diuretics, osmotic diuresis in hyperglycemia), dermal losses (burns, extensive sweating), or possibly sequestration of fluid, so-called third spacing (e.g., acute pancreatitis, muscle trauma). Renal perfusion may be impaired even in the setting of normal or even increased extracellular fluid. For example, renal perfusion may be reduced by a decreased cardiac output (heart failure) or by systemic arterial vasodilation with redistribution of cardiac output to extrarenal vascular beds (e.g., sepsis, liver cirrhosis).

Figure 66.1 Causes of AKI. AKI is classified into prerenal, renal, and postrenal causes. Renal causes of AKI should be considered under the different anatomic components of the kidney (vascular supply, glomerular, tubular, and interstitial disease). GBM, glomerular basement membrane.

Figure 66.2 Causes of AKI in the hospital setting. RPGN, rapidly progressive glomerulonephritis.

The presence of AKI in the setting of severe heart failure has been termed the cardiorenal syndrome and is often exacerbated by the use of ACE inhibitors and diuretics.

An unusual cause of prerenal AKI is the hyperoncotic state. Infusion of large quantities of osmotically active substances, such as mannitol, dextran, and protein, can increase the glomerular oncotic pressure enough to exceed the glomerular capillary hydrostatic pressure, which stops glomerular filtration, leading to an anuric form of AKI.

Prerenal azotemia can be corrected if the extrarenal factors causing the renal hypoperfusion are rapidly reversed. Failure to restore renal blood flow during the functional prerenal stage will ultimately lead to ischemic ATN and tubular cell injury.

PATHOPHYSIOLOGY AND ETIOLOGY OF POSTRENAL ACUTE KIDNEY INJURY

In any patient presenting with AKI, an obstructive cause must be excluded because prompt intervention can result in improvement or complete recovery of renal function (see Chapter 58). Postrenal forms of AKI are divided into intrarenal (tubular) and extrarenal. Tubular precipitation of insoluble crystals (phosphate, methotrexate, acyclovir, sulfonamides, indinavir, uric acid, triamterene, oxalic acid) or protein (hemoglobin, myoglobin, paraprotein) can increase intratubular pressure. If it is sufficiently high, this opposes glomerular filtration pressure and can decrease GFR. Similarly, obstruction of the extrarenal collecting system at any level (renal pelvis, ureters, bladder, or urethra) can lead to postrenal AKI. Obstructive uropathy is common in older men with prostatic disease and in patients with a single kidney or intra-abdominal, particularly pelvic, cancer. Severe ureteral obstruction is also seen with small inflammatory aortic aneurysms. Most causes of obstructive uropathy are amenable to therapy, and the prognosis is generally good, depending on the underlying disease.

PATHOPHYSIOLOGY OF ACUTE TUBULAR NECROSIS

ATN commonly occurs in high-risk settings, which include after vascular and cardiac surgery, severe burns, pancreatitis, sepsis, and chronic liver disease. ATN is responsible for most cases of

Figure 66.3 Renal pathology in acute tubular necrosis (ATN). **A**, Normal cortical renal tubules. **B** and **C**, ATN. Note the flattened epithelium, bare basement membranes, and intraluminal cellular debris. **D**, Recovering ATN showing a tubular epithelial cell mitotic figure (arrow). (Courtesy Erika Bracamonte, University of Washington, Seattle, USA.)

hospital-acquired AKI and is usually due to ischemic or nephrotoxic injury.^{3,4} In the intensive care unit, two thirds of cases of AKI are due to the combination of impaired renal perfusion, sepsis, and nephrotoxic agents.⁵

The importance of combined injurious mechanisms is also emphasized by experimental data. In animal studies, severe and prolonged hypotension (<50 mm Hg for 2 to 3 hours in the rat) does not cause ATN. Similarly, animal models require very high doses of single nephrotoxic agents to induce AKI. These features may reflect an inherent resistance to tubular injury in animal models but also illustrate the fact that a single insult alone is rarely sufficient to induce ATN. Fever may exacerbate ATN by increasing the renal tubular metabolic rate, thereby increasing adenosine triphosphate (ATP) consumption. In an experimental model (renal artery occlusion in the rat), renal ischemia for 40 minutes resulted in minimal renal injury at 32°C but marked renal injury at 39°C.

The typical course of uncomplicated ATN is recovery during 2 to 3 weeks. Superimposed renal insults often alter this pattern, however. For example, episodes of hypotension induced by hemodialysis may lead to additional ischemic lesions, potentially prolonging renal functional recovery, and patients with AKI often have multiple comorbidities.

Histology

The typical features of ATN on renal biopsy include vacuolization and loss of brush border in proximal tubular cells. Sloughing of tubular cells into the lumen leads to cast obstruction, manifested by tubular dilation. Interstitial edema can produce widely spaced tubules, and a mild leukocyte infiltration may be present (see Fig. 66.3).

Despite the term acute tubular “necrosis,” frankly necrotic cells are not a common finding on renal biopsy, and histologic evidence of injury frequently involves only 10% to 15% of the tubules despite marked functional impairment. This implies that factors other than just tubular cell injury (such as vasoconstriction and tubular obstruction) are important in the loss of GFR.

Tubular Injury in Acute Tubular Necrosis

The tubular damage is usually due to a combination of ischemic injury resulting in depletion of cellular ATP and direct tubular epithelial cell injury by nephrotoxins. Most accept that the S₃ segment of the proximal tubule and the medullary thick ascending limb (mTAL) are particularly vulnerable to

Figure 66.4 Sites of tubular injury in ATN. The S₃ segment of the proximal tubule and the medullary thick ascending limb are particularly vulnerable to ischemic injury because of the combination of borderline oxygen supply and high metabolic demands.

hypoxic injury (Fig. 66.4). There are several reasons for this vulnerability:

1. **Blood supply.** The blood flow to the kidney is not uniform, and most of it is directed to the renal cortex for glomerular filtration, where the cortical tissue PO₂ is 50 to 100 mm Hg. By contrast, the outer medulla and medullary rays are watershed areas receiving their blood supply from vasa recta. Countercurrent oxygen exchange occurs, leading to a progressive fall in PO₂ from cortex to medulla, which results in medullary cells living on the “brink of hypoxia” (medullary PO₂ as low as 10 to 15 mm Hg). The S₃ segments of proximal tubule cells and distal medullary thick ascending limbs are thus exposed to borderline chronic oxygen deprivation.
2. **High tubular energy requirements.** The cells of the S₃ region and mTAL have high metabolic activity, principally due to sodium reabsorption driven by basolateral membrane Na⁺,K⁺-ATPase. Indeed, blocking of sodium reabsorption in the mTAL with loop diuretics raises the medullary tissue PO₂ from about 15 to 35 mm Hg. Of note, the reduction of GFR in the setting of AKI may be renoprotective by diminishing sodium filtration and hence limiting ATP-dependent sodium reabsorption.
3. **Glycolytic ability of tubular cells.** Proximal tubular cells have minimal glycolytic machinery and rely almost solely on oxidative phosphorylation for the generation of ATP. In contrast, mTAL cells have a large glycolytic capacity and are more resistant to hypoxic or ischemic insults.

Hemodynamic Factors in the Development of Acute Tubular Necrosis

Impaired Renal Autoregulation

Autoregulation normally occurs between systolic blood pressures of 80 and 150 mm Hg, and between these ranges, renal blood flow, glomerular pressures, and GFR are maintained. Below 80 mm Hg, this autoregulation fails, and ischemic injury may result. In certain conditions, such as aging and chronic renal disease, autoregulation is abnormal, and ischemic injury may occur more easily with reductions in perfusion pressure. In addition, experimental studies demonstrate impaired autoregulation in ischemic ATN. In settings of low renal perfusion (e.g., volume depletion, left ventricular failure, edematous states, renal artery stenosis), GFR may be dependent on autoregulation mediated by vasodilatory prostaglandins acting on the afferent arteriole and angiotensin II-mediated efferent arteriolar vasoconstriction to maintain glomerular pressure. Any interference with these mechanisms (e.g., administration of ACE inhibitors or acute inhibition of cyclooxygenase 1 or 2 by NSAIDs) may produce a precipitous fall in GFR.

Intrarenal Vasoconstriction

In established ATN, renal blood flow is decreased by 30% to 50%. Indeed, in AKI, rather than the normal autoregulatory renal vasodilation that occurs in response to decreased perfusion pressure, there is evidence of renal vasoconstriction. A number of vasoconstrictors have been implicated in this vasoconstrictive

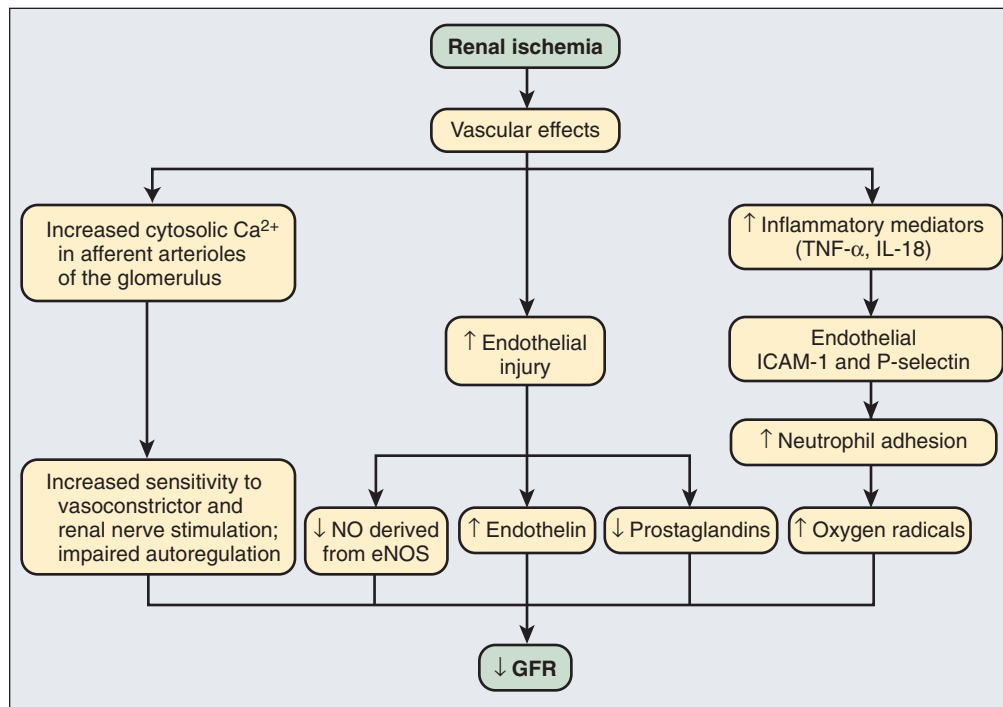

Figure 66.5 Vascular factors contributing to the development of acute tubular necrosis. ET, endothelin; ICAM-1, intercellular adhesion molecule 1; IL-18, interleukin-18; NO, nitric oxide; eNOS, endothelial nitric oxide synthase; PG, prostaglandin; TNF- α , tumor necrosis factor α . (Modified with permission from reference 31.)

response, including angiotensin II, endothelin 1, adenosine, thromboxane A₂, prostaglandin H₂, leukotrienes C₄ and D₄, and sympathetic nerve stimulation (Fig. 66.5). Tubuloglomerular feedback also contributes to this vasoconstriction. Some of these vascular abnormalities may be mediated by increased cytosolic calcium content in afferent arterioles as a result of ischemia, and disruption of the actin cytoskeleton in vascular smooth muscle cells may also impair autoregulation.

Tubuloglomerular Feedback

The role of tubuloglomerular feedback (see Chapter 2) in the setting of AKI may be partly beneficial because the resultant decrease in GFR limits sodium delivery to damaged tubules and decreases ATP-dependent tubular reabsorption, protecting against intracellular ATP depletion augmenting renal injury. In this respect, adenosine A₁ receptor knockout mice with absent tubuloglomerular feedback have augmented acute renal injury after ischemia-reperfusion.

Endothelial Cell Injury and the Development of Acute Tubular Necrosis

Renal cell injury is not limited to the tubular cell, and endothelial cell injury occurs partly as a result of acute renal ischemia and oxidant injury.³ Endothelial injury is characterized by cell swelling, upregulation of adhesion molecules (with enhanced leukocyte-endothelial cell interactions), and impaired vasodilation (decreased endothelial nitric oxide synthase and vasodilatory prostaglandins) and may mediate some of the impaired autoregulation and intrarenal vasoconstriction described earlier. Endothelial injury within the peritubular capillaries (vasa recta) may produce congestion in the outer medulla, exacerbating hypoxic injury to the S₃ segment of the proximal tubule and the thick ascending loop of Henle.

Tubular Epithelial Cell Injury and the Development of Acute Tubular Necrosis

The tubular cell may be injured because of ischemia, with resulting depletion of cellular energy stores (ATP), or from direct cytotoxic injury. After acute renal ischemia, tubular cell injury may also result from the restoration of renal blood flow (reperfusion injury). Mediators of tubular cell injury include reactive oxygen species (ROS), intracellular calcium influx, nitric oxide, phospholipase A₂, complement, and cell-mediated cytotoxicity. ROS may be derived from local sources (including xanthine oxidase and cyclooxygenases and secondary to mitochondrial injury) or from infiltrating leukocytes. In models of ischemic ATN, a variety of methods that inhibit ROS protect against renal injury.⁶

Factors that affect the integrity and function of the renal tubular epithelial cells and contribute to the reduction in GFR include the following (Fig. 66.6):

1. Cell death. Despite the term acute tubular “necrosis,” only a small percentage of tubular cells undergo cell death, and of these, many actually die by apoptosis rather than by necrosis. Indeed, studies in animal models have shown amelioration of renal injury with caspase inhibitors that inhibit apoptosis.
2. Disruption of actin cytoskeleton. A characteristic feature of sublethally injured cells is the disruption of the actin cytoskeleton. Activation of the cysteine protease calpain (partly due to increased intracellular calcium) can degrade actin-binding proteins such as spectrin and ankyrin. This leads to abnormal translocation of Na⁺,K⁺-ATPase and other proteins from the basolateral membrane to the cytoplasm or apical membranes. In the proximal tubular cell, this loss of polarity results in impaired proximal reabsorption of filtrate with increased distal NaCl delivery and activation of tubuloglomerular feedback.

Figure 66.6 Tubular factors in the development of acute tubular necrosis. Loss of cell polarity weakens cell-cell and cell-matrix adhesion, resulting in cast obstruction and backleak of tubular fluid. (Modified from reference 4.)

3. Cast obstruction. Tubular cells are attached to the tubular basement membrane by $\alpha_3\beta_1$ integrins, which recognize RGD (arginine-glycine-aspartate) sequences in matrix proteins. Disruption of the actin cytoskeleton results in movement of integrins from basolateral positions to the apical membrane, leading to impaired cell matrix adhesion and cell detachment. Many of these detached cells are still viable and can be cultured from urine of patients with ATN. Sloughed proximal tubular cells can bind to RGD sequences in Tamm-Horsfall protein, resulting in cast formation and intratubular obstruction. In models of ischemic AKI, the elevation in tubular pressures may be inhibited by synthetic RGD peptides, mitigating the obstructive process.
4. Backleak. The loss of adhesion molecules (E-cadherin) and tight junction proteins (ZO-1, occludin) results in the weakening of junctions between cells, allowing filtrate to leak back into the renal interstitium. Although this does not alter the actual GFR at the level of the glomerulus, the net effect is a reduction in the measured GFR. Earlier dextran sieving experiments suggest only a modest effect of backleak on the decrement of GFR in AKI (about 10%); however, in the renal allograft with delayed graft function due to severe ATN, backleak has been calculated to account for up to 50% of the reduction in inulin clearance.

Inflammatory Factors in the Development of Acute Tubular Necrosis

The inflammatory response plays an important role in ATN.⁷ Several proinflammatory cytokines (such as tumor necrosis factor α [TNF- α], interleukins IL-6 and IL-1 β) and chemokines (such as MCP-1, IL-8, RANTES) are generated within the kidney and promote the infiltration of leukocytes. Renal hypoxia directly induces epithelial cells to produce some of these mediators. Ischemic injury also activates innate immune systems, including the complement system and Toll-like receptors 2 and 4 (TLR2 and TLR4). Activation of complement can cause direct injury of the renal tubular epithelial cells, and signaling through complement receptors and the Toll-like receptors induces the epithelial cells to produce chemokines.

Neutrophils and mononuclear cells may be seen in peritubular capillaries on renal biopsy. Experimental studies have helped to elucidate the role of the inflammatory cells in ATN. Neutrophil activation with the release of proteases and ROS can exacerbate injury. By contrast, neutrophil depletion with antibody, or inhibition of neutrophil adhesion molecules (ICAM-1) with antibody or antisense oligonucleotides, ameliorates injury in ischemic ATN. ICAM-1 knockout mice are similarly protected.

More recently, a role of T lymphocytes has emerged. Experimental ischemia-reperfusion injury may be ameliorated by T-cell depletion or blockade of T-cell costimulatory pathways. In addition, CD4-deficient mice (helper T cells) or mice that are unable

to mount a Th1 response are protected against ischemia-reperfusion injury.

Recovery Phase

Recovery from ATN requires the restoration of tubular cell number and coverage of denuded tubular basement membrane. A marked increase in cell proliferation occurs in recovering human ATN, and mitotic figures may be seen by light microscopy (see Fig. 66.3). There has been some debate about the origin of the restored tubular cells. Some studies have suggested that mesenchymal stem cells may locate to areas of tubular injury and transform into proximal tubular cells. Indeed, experimental models of ischemia-reperfusion injury may be ameliorated by infusions of mesenchymal stem cells. More recent evidence, however, suggests that the restoration of tubular cell number is due to the dedifferentiation and proliferation of surviving tubular cells.⁸ A number of growth factors have been implicated in the proliferative response, including insulin-like growth factor 1 (IGF-1) and hepatocyte growth factor; however, a therapeutic trial of subcutaneous recombinant IGF-1 in critically ill patients failed to show an acceleration in renal functional recovery.⁹ After tubular epithelial cell proliferation, the dedifferentiated cells must migrate to areas of denuded tubular basement membrane, attach to the basement membrane, and differentiate into mature polar tubular epithelial cells.

SPECIFIC CAUSES OF ACUTE KIDNEY INJURY

Nephrotoxic Agents and Mechanisms of Toxicity

The avoidance of nephrotoxic agents in AKI is critical in the management of this condition because AKI may be rapidly reversible on removal of the offending agent. The mechanisms of nephrotoxicity are very broad and include alterations in renal hemodynamics, induction of direct tubular injury, generation of allergic reactions resulting in interstitial nephritis, and intratubular obstruction. The list is extensive, but the more common agents are presented in Figure 66.7.

Nonsteroidal Anti-inflammatory Drugs

NSAIDs are a common cause of AKI in the community because of the large amounts of these drugs either prescribed or bought over-the-counter.¹⁰ The newer cyclooxygenase 2 (COX-2)-specific NSAIDs have effects on renal function similar to those of the nonselective NSAIDs.

This NSAID-related AKI may be due to a hemodynamically mediated reduction in GFR in particular clinical situations, such as atherosclerotic cardiovascular disease in elderly patients, pre-existing chronic renal insufficiency, states of renal hypoperfusion (including sodium depletion, diuretic use, and hypotension), and sodium-avid states (such as cirrhosis, nephrotic syndrome, and congestive heart failure). There is little evidence that NSAIDs impair renal function in otherwise healthy individuals. This form of AKI is usually reversible in 2 to 7 days on discontinuation of the drug. Less frequently, NSAIDs induce ATN or, even more rarely, papillary necrosis.¹⁰ NSAIDs, including the COX-2-specific NSAIDs, may also cause an acute interstitial nephritis (see Chapter 60). Other renal side effects of NSAIDs include fluid and electrolyte disturbances such as sodium retention exacerbating hypertension and congestive heart failure, hyponatremia, and hyperkalemia.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

ACE inhibitors and ARBs may also cause a hemodynamically induced AKI in the setting of reduced renal perfusion due to impaired vasoconstriction of the efferent arteriole. They may also directly impair renal perfusion by their antihypertensive effects. Patients in whom renal perfusion is compromised because of dehydration, renovascular disease, or functionally impaired autoregulation are at risk for development of AKI after initiation of therapy with ACE inhibitors or ARBs.

Patients chronically treated with ACE inhibitors have an increased risk for postoperative renal dysfunction,¹¹ probably as a consequence of intraoperative hypotensive episodes.

Gentamicin

Gentamicin is excreted by glomerular filtration, and toxicity may occur if the dose is not adjusted for underlying renal impairment. Cationic amino groups (NH_4^+) on the drug bind to anionic megalin on the brush border of proximal tubular epithelial cells, and the drug is then internalized by endocytosis. The drug accumulates in proximal tubular cell lysosomes and can reach 100 to 1000 times its serum concentration. The drug interferes with cellular energetics, impairs intracellular phospholipases, and induces oxidative stress; however, the exact pathways culminating in tubular necrosis remain unknown.¹²

Nonoliguric AKI usually occurs after 5 to 10 days of treatment with gentamicin. Involvement of distal tubular segments may produce polyuria and potassium and magnesium wasting. The risk for AKI correlates with the accumulation of gentamicin in proximal tubular cells and is related to the daily dose and duration of therapy. Prolonged accumulation in proximal tubular cells may allow development of AKI even after the drug has been discontinued. Additional risk factors for gentamicin toxicity include increasing age, preexisting renal disease, hypotension, concurrent liver disease, sepsis syndrome, and concurrent nephrotoxins.

Gentamicin serum levels should be followed to minimize nephrotoxicity. When possible, the drug may be administered in a single daily total dose, which leads to lower renal proximal tubular cell accumulation. Gentamicin, tobramycin, and netilmicin appear to have similar nephrotoxic effects. Amikacin, which has fewer amino groups per molecule, may be less nephrotoxic.

The macrolide antibiotic vancomycin has only rarely been associated with AKI when it is used as monotherapy, typically with toxic serum drug levels. However, when it is used with gentamicin, it may increase the risk for aminoglycoside-induced AKI.

Amphotericin

This polyene macrolide antibiotic binds to sterols in the cell membranes of fungal walls (ergosterol) and mammalian (cholesterol) cell membranes, resulting in the formation of aqueous pores, which increase membrane permeability. The increased sodium influx leads to increased Na^+ , K^+ -ATPase activity and depletion of cellular energy stores. In addition, the standard amphotericin formulation is suspended in the bile salt deoxycholate, which has a detergent effect on cell membranes.¹³ Nephrotoxicity relates to cumulative dosage, usually occurring after administration of 2 to 3 g.

Figure 66.7 Common nephrotoxic agents leading to acute kidney injury. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; NSAIDs, nonsteroidal anti-inflammatory drugs.

Early signs of nephrotoxicity include a loss of urine concentrating ability, followed by a decrease in GFR. Hypokalemia and hypomagnesemia due to distal tubular toxicity are common. A distal renal tubular acidosis may be due to proton backleak in the cortical collecting duct.

Prevention of nephrotoxicity requires the maintenance of high urine flow rates by saline loading during amphotericin administration. The more expensive liposomal amphotericin preparations reduce the incidence of AKI by 50%. The binding of amphotericin to ergosterol is more avid than to cholesterol, and by delivery of the drug as a cholesterol liposome, diminished binding to

tubular epithelial cell membranes results without altering fungal binding. In addition, liposomal preparations do not contain deoxycholate. Amphotericin-induced AKI is usually reversible with discontinuation of treatment with the drug, although distal tubular injury as manifested by magnesium wasting may persist.

Antiviral Therapy

Acyclovir

Nephrotoxicity is typically seen after intravenous acyclovir administration and may be due to direct tubular cell toxicity and

the formation of intratubular acyclovir crystals, which appear as birefringent needle-shaped crystals on urine microscopy. However, crystals may also be seen in non-AKI patients, and renal biopsy data suggest that acute interstitial nephritis may be the predominant mechanism of toxicity. Ceftriaxone appears to increase the risk for nephrotoxicity. By contrast, ganciclovir has little nephrotoxicity.

Oliguric AKI typically occurs within a few days of treatment and may be associated with abdominal or loin pain. High serum levels of acyclovir due to decreased renal clearance may produce neurologic toxicity. The AKI is usually mild and recovers on stopping of the drug.

Foscarnet

Foscarnet is a phosphate analogue used in the treatment of severe cytomegalovirus infection but also inhibits proximal tubule sodium-phosphate cotransport. AKI occurs in 10% to 20% of treated patients and may be due to ATN or intratubular crystal obstruction and acute interstitial nephritis. The AKI is usually nonoliguric and associated with mild proteinuria (<1 g) and a benign urine sediment. Hypocalcemia due to chelation of calcium may be present. The renal failure is usually reversible, although recovery may take several months. Prehydration markedly decreases the incidence of AKI.

Cidofovir and Adefovir

These nucleotide analogues have been associated with AKI secondary to proximal tubular injury in 12% to 24% of cases. They are transported into the proximal tubule by the human organic anion transporter (hOAT), and nephrotoxicity may be reduced by concurrent use of probenecid, which blocks hOAT and volume expansion.

Other Antiviral Agents

Most other antiviral agents are not nephrotoxic. In the treatment of hepatitis C, there have been rare reports of ATN secondary to interferon alfa.

Immunosuppressive Agents

See also Chapter 97.

Calcineurin Inhibitors

Cyclosporine and tacrolimus may cause acute renal impairment due to afferent arteriolar vasoconstriction partly mediated by endothelin. This is usually reversible on dose reduction. Persistent injury may lead to chronic interstitial fibrosis in a striped pattern along medullary rays, reflecting the ischemic nature of the insult as well as the development of arteriolar hyalinosis. Associated clinical features may include hypertension, hyperkalemia, hyperuricemia, and wasting of phosphate and magnesium from tubular injury. Calcineurin inhibitors may also cause endothelial injury, leading to thrombotic microangiopathy (see Chapter 28).

Other Immunosuppressive Agents

The monoclonal anti-CD3 antibody OKT3 or polyclonal antilymphocyte and antithymocyte preparations may cause a first-dose cytokine release syndrome and prerenal azotemia secondary to capillary leak. OKT3 has rarely been associated with a hemolytic-uremic syndrome. Intravenous immune globulin can cause AKI, which may be partly mediated by the high sucrose concentration in these products. Tubular uptake of sucrose may

result in osmotic cell swelling and injury. Methotrexate is toxic to proximal tubular epithelial cells and rarely may cause intratubular crystal obstruction.

Acetaminophen (Paracetamol)

Isolated ATN with acetaminophen may occur in rare cases, but renal injury is more typically associated with acute hepatitis. Renal and liver toxic effects usually occur when more than 15 g has been taken, but in alcoholics, normal doses may be toxic. Acetaminophen is conjugated in the liver and undergoes renal excretion. Less than 5% undergoes metabolism by P-450 (CYP2E1) enzymes to form a toxic metabolite, *N*-acetylimidoquinone, which is inactivated by the thiol group of glutathione. With high levels of acetaminophen, glutathione becomes depleted, and *N*-acetylimidoquinone can bind to thiol groups on intracellular proteins, resulting in cell injury. Because glutathione is a major intracellular antioxidant, its loss may predispose to oxidative injury to the tubular cells.

Clinically, acute hepatitis and ATN only begin once glutathione levels are depleted, and clinical manifestations usually present 3 to 4 days after ingestion. *N*-Acetylcysteine can be protective, if it is administered early, because it provides a free thiol group, substituting for glutathione.

Ethylene Glycol

Ethylene glycol, found in antifreeze, remains a cause of both deliberate and accidental injury. It is rapidly metabolized by alcohol dehydrogenase to glycoaldehyde and glyoxylate, which are toxic to tubular cells. Further metabolism generates oxalic acid, which can precipitate in renal tubules, leading to intratubular obstruction.

The diagnosis is suggested by the presence of a severe anion gap metabolic acidosis and the presence of a serum osmolal gap. Oxalate crystals are typically but not always seen on urine microscopy (see Chapter 4, Fig. 4.7). Management includes inhibition of alcohol dehydrogenase with intravenous ethanol (aiming for blood levels of 100 to 200 mg/dl) or the specific alcohol dehydrogenase inhibitor fomepizole. Hemodialysis should be performed to remove the ethylene glycol and metabolites when the level is above 20 mg/dl and continued until it is below 5 mg/dl. Methanol intoxication may present with similar metabolic abnormalities but rarely causes AKI (see Chapter 12).

Illicit Drug Use

AKI is a common condition in those who abuse drugs. It may be due to nephrotoxicity of the drug, coexistent viral infection (human immunodeficiency virus [HIV] infection, hepatitis C virus [HCV] infection), sepsis, infective endocarditis, rhabdomyolysis, or alcohol abuse.

Cocaine induces intense vasoconstriction, which may lead to severe hypertension and rhabdomyolysis.¹⁴ Mechanisms for rhabdomyolysis include coma and pressure necrosis, vasospasm leading to ischemic muscle injury, and adrenergic stimulation and hyperpyrexia leading to increased cellular metabolism. It typically occurs in those who inject cocaine, and the patient often presents with fever, hypertension, tachycardia, and a decreased mental state.

Other illicit drugs associated with AKI include opiates (coma-associated, pressure-induced rhabdomyolysis), phencyclidine (PCP; rhabdomyolysis secondary to hyperpyrexia and

vasoconstriction), heroin (rhabdomyolysis), and amphetamines (AKI secondary to rhabdomyolysis, acute interstitial nephritis, or acute necrotizing angitis).

Bisphosphonates

AKI due to tubular injury has been described with intravenous bisphosphonates (especially zoledronate and pamidronate), but not oral. This typically occurs after several months of treatment.

Bowel Preparations (Oral Sodium Phosphate and Polyethylene Glycol–Electrolyte Lavage Solution)

Bowel preparation for colonoscopic procedures is usually performed by the oral administration of high-osmolar agents such as oral sodium phosphate. These agents have been associated with the development of electrolyte disturbances, AKI, and chronic kidney disease (CKD).¹⁵ AKI associated with oral sodium phosphate, also referred to as phosphate nephropathy, is believed to be caused by phosphaturia and calcium phosphate deposition within the renal tubules. This occurs most frequently in patients with CKD.

Occupational Toxins

Heavy Metals

Lead intoxication usually causes a chronic nephropathy (see Chapter 62). Rarely, acute tubular injury occurs that may be associated with Fanconi syndrome. ATN may also occur in cadmium and mercury poisoning.

Organic Solvents

Organic solvents may cause acute tubular injury by peroxidation of membrane lipids. A subacute renal failure due to anti-glomerular basement membrane (anti-GBM) antibody disease has also been reported with exposure to halogenated hydrocarbons.

Herbal Remedies

Specific herbs used in traditional African medicine (e.g., Cape aloes, *Callilepis laureola*) are common causes of AKI in parts of Africa. A subacute form of renal failure due to aristolochic acid found in certain herbs used in traditional Chinese medicine has also been described (see Chapter 62).

HEME PIGMENT NEPHROPATHY

Heme pigment nephropathy is a common cause of AKI and usually secondary to the breakdown of muscle fibers (rhabdomyolysis), which release potentially nephrotoxic intracellular contents (particularly myoglobin) into the systemic circulation. Less commonly, heme pigment nephropathy may be due to massive intravascular hemolysis. Prevention of and therapy for heme pigment nephropathy are discussed in Chapter 69.

Causes of Rhabdomyolysis

Muscle trauma is the most common cause of rhabdomyolysis. The initial description was by Bywaters and Beall during the bombing of London in World War II.¹⁶ Other common causes of muscle injury include marked exercise, seizures, pressure

Causes of Rhabdomyolysis	
Muscle injury/ischemia	Trauma, pressure necrosis, electric shock, burns, acute vascular disease
Myofiber exhaustion	Seizures, excessive exercise, heat exhaustion
Toxins	Alcohol, cocaine, heroin, amphetamines, ecstasy, phencyclidine, snakebite
Drugs	Statins, fibrates, zidovudine, neuroleptic malignant syndrome, azathioprine, theophylline, lithium, diuretics
Electrolyte disorders	Hypophosphatemia, hypokalemia, excess water shifts (hyposmolality)
Infections	Viral (influenza, HIV, Coxsackievirus, Epstein-Barr virus), bacterial (<i>Legionella</i> , <i>Francisella</i> , <i>Streptococcus pneumoniae</i> , <i>Salmonella</i> , <i>Staphylococcus aureus</i>)
Familial	McArdle's disease, carnitine palmitoyl transferase deficiency, malignant hyperthermia
Other	Hypothyroidism, polymyositis, dermatomyositis

Figure 66.8 Causes of rhabdomyolysis.

necrosis secondary to coma, alcohol abuse, and limb ischemia (Fig. 66.8). In skeletal muscles confined to rigid compartments, cell swelling after injury may result in increased intracompartmental pressures impairing local microvascular circulation, leading to compartment syndrome (Fig. 66.9). In the patient with alcohol abuse, rhabdomyolysis is often multifactorial. Contributing causes include pressure necrosis from coma (“found down”), direct myotoxicity from ethanol, seizures, and electrolyte abnormalities (hypokalemia and hypophosphatemia). Therapy with statins may be associated with rhabdomyolysis. The risk is increased by concomitant therapy with fibrates, cyclosporine, or erythromycin. Familial myopathies such as McArdle's syndrome and carnitine palmitoyltransferase deficiency should be suspected in patients with a history of recurrent episodes of rhabdomyolysis associated with muscle pain, positive family history, onset in childhood, and absence of other identifiable causes.¹⁷

Causes of Hemoglobinuria

Intravascular hemolysis results in circulating free hemoglobin. If the hemolysis is mild, the released hemoglobin is bound by circulating haptoglobin. With massive hemolysis, however, haptoglobin becomes exhausted. Hemoglobin (69 kD) then dissociates into $\alpha\beta$ dimers (34 kD) that are small enough to be filtered, resulting in hemoglobinuria, hemoglobin cast formation, and heme uptake by proximal tubular cells. Like myoglobin, these processes can result in ATN and filtration failure. Causes of hemoglobinuric AKI include incompatible blood transfusion, autoimmune hemolytic anemia, malaria (blackwater fever), glucose-6-phosphate dehydrogenase deficiency, paroxysmal nocturnal hemoglobinuria, march hemoglobinuria, and toxins (dapsone, venoms).

Pathogenesis of Heme Pigment Nephropathy

The renal injury is due to a combination of factors, including volume depletion, renal vasoconstriction, direct heme protein–

Figure 66.9 Compartment syndrome. **A**, Severe calf swelling due to anterior and posterior compartment syndromes after ischemia-reperfusion. **B**, Appearance after emergency fasciotomy. Note edematous muscle and hematoma. (Courtesy Michael J Allen, FRCS, Leicester, UK.)

mediated cytotoxicity, disseminated intravascular coagulation, and intraluminal cast formation (Fig. 66.10). Volume depletion is often prominent in patients with rhabdomyolysis owing to the sequestration of large amounts of fluid (up to 15 to 20 liters) in injured muscle. Volume depletion activates the sympathetic nervous system and renin-angiotensin system (RAS), resulting in renal vasoconstriction. This may be exacerbated by the scavenging of nitric oxide by circulating heme proteins. Myoglobin (17 kd) is freely filtered at the glomerulus and is toxic to tubular epithelial cells. The heme center of myoglobin may directly induce lipid peroxidation and renal injury,¹⁸ and liberated free iron catalyzes the formation of hydroxyl radical through the Fenton reaction, inducing free radical-mediated injury. Renoprotection has been demonstrated in animal models with free iron scavengers and various antioxidants. Finally, the precipitation of myoglobin with Tamm-Horsfall protein and sloughed proximal tubular cells may result in obstructing casts in the distal

nephron. This is enhanced by increased concentrations of tubular heme protein due to volume depletion with low tubular fluid flow rates. The binding of myoglobin to Tamm-Horsfall protein is enhanced in acidic urine.

Clinical features, prevention, and therapy are described in Chapters 68 to 70.

RADIOCONTRAST-INDUCED NEPHROPATHY

AKI secondary to contrast nephrotoxicity typically occurs in patients with underlying renal impairment and is rarely seen in patients with normal renal function.¹⁹ It may occur with both intravenous and intra-arterial administration of contrast material but not with oral administration (assuming an intact bowel). The incidence of contrast nephropathy is about 20% and 50% in patients with serum creatinine levels above 2 mg/dl and 5 mg/dl (176 and 440 $\mu\text{mol/l}$), respectively. Other risk factors for the development of this condition include diabetic nephropathy, advanced age (>75 years), congestive heart failure, volume depletion, and high or repetitive doses of radiocontrast agent. A high-osmolar contrast agent is more nephrotoxic than low-osmolar or iso-osmolar contrast agents are. Concurrent use of potentially nephrotoxic agents, such as NSAIDs or ACE inhibitors, may increase the risk.

Pathogenesis

Medullary hypoxia and direct tubular epithelial cell toxicity are the main factors in the pathogenesis of contrast nephropathy. Typically, a biphasic hemodynamic response is seen. An initial vasodilation (lasting a few seconds to minutes) is followed by a more prolonged renal vasoconstriction. The consequent medullary hypoxia may be exacerbated by the osmotic diuresis, leading to increased sodium delivery to the medullary thick ascending loop and requiring greater oxygen consumption for reabsorption.

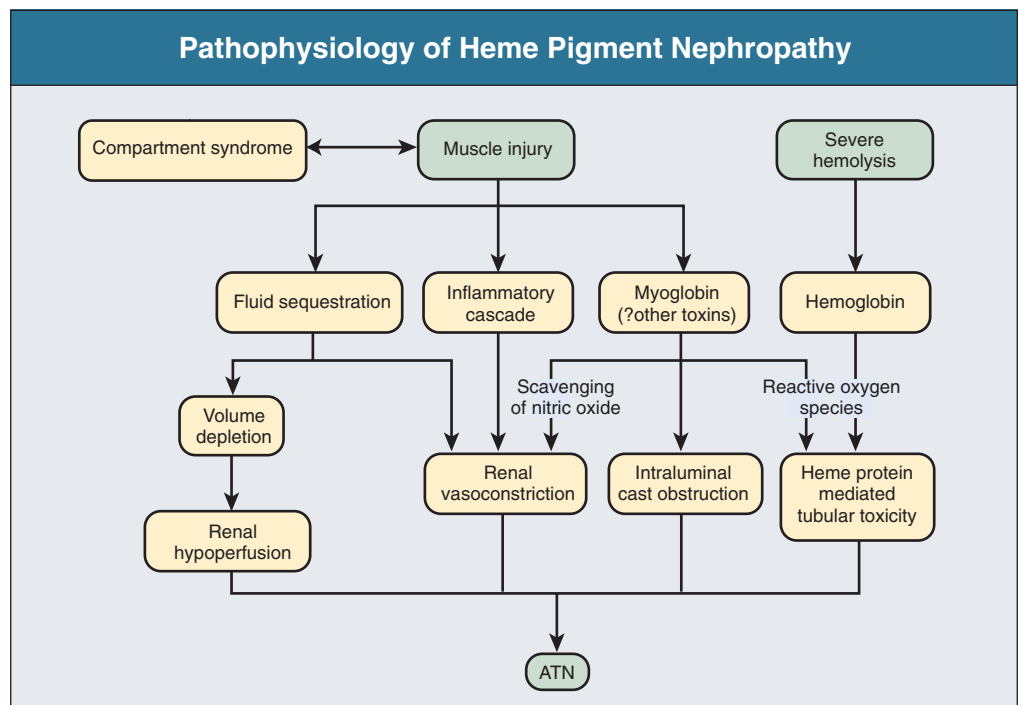

Radiocontrast agents also cause direct tubular epithelial cell injury. Human studies have demonstrated low-molecular-weight proteinuria, suggestive of proximal tubular injury, partly mediated by ROS. Increased markers of lipid peroxidation have been described, and the administration of antioxidants ameliorates contrast nephropathy in animals.

Clinical features, prevention, and therapy are described in Chapters 68 to 70.

ATHEROEMBOLIC RENAL DISEASE (SYNDROME OF MULTIPLE CHOLESTEROL EMBOLI)

This underrecognized condition occurs predominantly in older patients with atherosclerotic vascular disease, either spontaneously or, more frequently, precipitated by arteriography, vascular surgery, thrombolysis (streptokinase and tissue plasminogen activator), and anticoagulation. Destabilization of atherosclerotic plaques primarily in the aorta results in showers of cholesterol that lodge in small arteries in the kidneys (see Fig. 64.15) and the lower extremities (see Fig. 64.13). Characteristic needle-shaped clefts may be seen on renal or skin biopsy, denoting the localization of cholesterol plaques before dissolution with tissue fixation. The cholesterol emboli produce a marked and progressive inflammatory reaction, resulting in occlusion of the involved vasculature. Renal atheroembolism is discussed further in Chapter 64.

Figure 66.10 Pathophysiology of heme pigment nephropathy. ATN, acute tubular necrosis.

OTHER VASCULAR CAUSES OF ACUTE KIDNEY INJURY

AKI caused by complete renal artery thrombosis occurs when the occlusion is bilateral or, in the case of unilateral acute occlusion, with a single nonfunctioning kidney. Thrombosis of the renal artery or its intrarenal branches and noncholesterol emboli are more common in elderly patients. One important risk for intrarenal emboli is the presence of atrial fibrillation, in which the relative risk for peripheral embolization (aorta, renal and pelvic arteries, and arteries of the extremities) has been calculated to be 4.0 in men and 5.7 in women compared with the general population.

Renal vein thrombosis most commonly occurs in the setting of nephrotic syndrome and rarely may cause AKI if it is bilateral (see Chapter 64).

ACUTE INTERSTITIAL NEPHRITIS

This is most commonly a drug-induced phenomenon and is an important differential diagnosis in AKI because removal of the offending agent can result in reversal of the condition. Less commonly, it may be due to infection or immune-mediated diseases. Acute interstitial nephritis is discussed further in Chapter 60.

THROMBOTIC MICROANGIOPATHY

Thrombotic microangiopathy (TMA) constitutes a wide range of conditions that should be considered when a patient presents with AKI and thrombocytopenia, although the condition may occur in the absence of a low platelet count (see Figs. 28.10 and 28.12). Endothelial activation is followed by the formation of platelet thrombi, which occlude small vessels and lead to downstream ischemic injury. Endothelial injury may be triggered by infections, drugs, or immune complexes. Patients with reduced

von Willebrand factor protease activity or impaired regulation of the complement system are at increased risk for development of TMA. Renal biopsy may be required to confirm the diagnosis, although histology is unable to differentiate among the different causes of TMA. TMA is discussed further in Chapter 28.

SPECIFIC CLINICAL SITUATIONS

Determination of the etiology of AKI is often aided by recognizing common patterns of presentation and determining the likely causes arising in each of these situations.

Acute Kidney Injury in the Patient with Multiorgan Failure

About 20% of patients with sepsis syndrome and 50% of those with septic shock develop AKI. This significantly worsens the prognosis, and when dialysis is required, intensive care unit mortality increases to 45% to 80%. Sepsis is classically associated with infection. A similar condition, termed the systemic inflammatory response syndrome (SIRS), may occur secondary to non-infectious insults such as acute pancreatitis, major trauma, and ischemia-reperfusion. Activation of the innate immune system may occur after the interaction of a number of bacterial products (lipopolysaccharide, flagellin, lipoteichoic acid, others) with pattern recognition receptors (such as Toll-like receptors) on immune cells. This leads to the activation of a wide range of cellular and humoral mediator systems, including the cytokine cascade (TNF- α , IL-1 β , IL-6); the complement, coagulation, and fibrinolytic systems; and the release of mediators such as eicosanoids, platelet-activating factor, endothelin 1, and nitric oxide. Widespread endothelial injury results, leading to peripheral vasodilation, increased vascular permeability, and leukocyte infiltration. Peripheral vasodilation causes hypotension, with consequent activation of the RAS, increased vasopressin, and increased cardiac output to maintain organ perfusion. This

neurohormonal activation may constrict the afferent arterioles of the kidney and further impair renal perfusion. The causes of the AKI in this setting are typically multifactorial, due to a combination of hypotension, impaired renal perfusion, inflammatory mediators, and nephrotoxic agents.²⁰⁻²³

Acute Kidney Injury in the Postoperative Patient

AKI in the postoperative period is commonly due to problems with fluid balance, perioperative hemodynamic instability, or nephrotoxic agents. The critically ill postoperative patient may develop SIRS. AKI may be particularly common after vascular, cardiac, and hepatobiliary surgery.

There is evidence that anesthetic agents may impair renal function. This may be partly due to their hypotensive effects, but the metabolism of fluorinated agents can lead to the production of potentially nephrotoxic fluoride ions. Modern inhaled agents (e.g., isoflurane, halothane, enflurane) all cause a transient decrease in GFR, and methoxyflurane had to be discontinued because of nephrotoxicity.

After Vascular Surgery

In patients with peripheral vascular disease, prior ischemic renal disease is often present, and preoperative diminished renal function is the strongest predictor of the risk for postoperative AKI. In aortic aneurysm surgery, most aneurysms are infrarenal; however, surgery that directly involves the renal arteries or aortic cross-clamping above the renal arteries can result in severe renal ischemia. Furthermore, aortic manipulation may dislodge atherosclerotic plaque, resulting in renal atheroembolism. Peripheral limb surgery may be complicated by rhabdomyolysis, and radiocontrast dye is frequently used for diagnostic purposes.

After Cardiac Surgery

Risk factors for postoperative AKI include duration of cardiac bypass, preoperative renal function, age, diabetes, valvular surgery, blood transfusions, and poor cardiac function.²⁴ Even a minor increase in serum creatinine after cardiac surgery is independently associated with an increased mortality and cost. The surgery is often performed with the patient cooled to less than 30°C to protect cells against ischemic injury; however, systemic hypothermia may cause intravascular coagulation. Aortic instrumentation and clamping may lead to renal atheroembolism. Cardiac bypass causes exposure of blood to a nonendothelialized surface, resulting in activation of neutrophils, platelets, complement, and fibrinolytic systems. Significant hemolysis may also occur, potentially resulting in hemoglobinuria. Perioperative myocardial infarction or left ventricular dysfunction may impair renal perfusion postoperatively, although the low cardiac output is often transient and recovers within 24 to 48 hours. Atrial fibrillation is a common complication and may be associated with peripheral embolization. Studies have suggested that off-pump coronary artery bypass operations have a lower risk of AKI than surgeries in which patients are put on cardiopulmonary bypass.

After Hepatobiliary Surgery

Surgery to relieve obstructive jaundice is more commonly associated with AKI than are other forms of abdominal surgery. This may be due to the absence of bile salts in the gut lumen, which normally break down lipopolysaccharide endotoxin, preventing absorption. One study suggested a decreased incidence of postoperative endotoxemia with treatment with oral bile salts. Other factors may include direct nephrotoxic effects of bilirubin or

Causes of Pulmonary-Renal Syndrome

Systemic vasculitis	Anti-GBM disease (Goodpasture's) ANCA associated <ul style="list-style-type: none"> • Wegener's granulomatosis • Microscopic polyarteritis • Churg-Strauss syndrome • Drugs (penicillamine, hydralazine, propylthiouracil) Immune complex disease <ul style="list-style-type: none"> • Lupus erythematosus • Henoch-Schönlein purpura • Mixed cryoglobulinemia • Rheumatoid vasculitis
Infection	Severe bacterial pneumonia; postinfectious glomerulonephritis; <i>Legionella</i> ; hantavirus; opportunistic infection in immunocompromised patients; infective endocarditis
Pulmonary edema and AKI	Volume overload; severe left ventricular failure
Multiorgan failure	Acute respiratory distress syndrome and AKI
Other	Paraquat poisoning; renal vein or IVC thrombosis with pulmonary emboli

Figure 66.11 Causes of pulmonary-renal syndrome. ANCA, anti-neutrophil cytoplasmic antibody; GBM, glomerular basement membrane; IVC, inferior vena cava.

bile salts on renal tubular cells and an increased incidence of biliary sepsis.

Abdominal Compartment Syndrome

Markedly raised intra-abdominal pressures (>20 mm Hg) may occur after trauma, after abdominal surgery, or secondary to massive fluid resuscitation and can cause AKI.²⁵ The mechanism remains unclear but may be due to increased renal venous pressure and vascular resistance. Ureteral compression is not considered a factor. Efforts to reduce intra-abdominal pressures, including paracentesis, nasogastric suction, ultrafiltration, and surgical decompression, may occasionally improve renal function.

Pulmonary-Renal Syndromes

The term *pulmonary-renal syndrome* describes the presence of pulmonary hemorrhage in a patient with AKI and is most commonly due to anti-GBM disease (Goodpasture's syndrome), systemic vasculitis, or systemic lupus erythematosus (Fig. 66.11; see Chapters 23 to 25).

A similar clinical presentation may be due to pulmonary edema secondary to volume overload in AKI. Other conditions that may masquerade as a pulmonary-renal syndrome include upper respiratory infection triggering a flare of IgA nephropathy, severe bacterial pneumonia complicated by ATN or postinfectious glomerulonephritis, *Legionella* species infection causing a severe atypical pneumonia, and acute interstitial nephritis or rhabdomyolysis.

Acute Kidney Injury and Liver Disease

The patient with liver cirrhosis is predisposed to the development of AKI, and the differential diagnosis typically falls between prerenal azotemia, hepatorenal syndrome, and ATN. Assessment

Causes of Acute Kidney Injury and Liver Disease	
Prerenal uremia	Diuretic use, gastrointestinal loss, peritoneal aspiration, hypoalbuminemia
Hepatorenal syndrome	
Acute tubular necrosis	Hyperbilirubinemia, sepsis, toxic shock syndrome
Drugs	Acetaminophen (paracetamol), NSAIDs, tetracycline, rifampicin, isoniazid, anesthetic agents, sulfonamides, allopurinol, methotrexate
Infections	Hepatitis C and cryoglobulinemia, hepatitis B and polyarteritis nodosa, leptospirosis, hantavirus, Epstein-Barr virus, gram-negative sepsis, spontaneous bacterial peritonitis
Other	Papillary necrosis and obstruction, inhalation of chlorinated hydrocarbons, mushroom poisoning (<i>Amanita phalloides</i>)

Figure 66.12 Causes of acute kidney injury and liver disease. NSAIDs, nonsteroidal anti-inflammatory drugs.

of intravascular volume status can be difficult, and a therapeutic trial of volume replacement is typically undertaken. Impaired renal perfusion and hyperbilirubinemia are predisposing risk factors. Alternatively, the same etiologic agent may be responsible for both the liver and renal injury. This occurs with certain infections (e.g., leptospirosis, hantavirus) and nephrotoxic agents (Fig. 66.12). Rarely, hyperbilirubinemia from hemolysis may cause jaundice in the absence of liver disease. AKI in patients with liver disease is discussed further in Chapter 72.

Acute Kidney Injury in Patients with HIV Infection

AKI is common in patients with HIV infection and may be related to the disease itself (e.g., HIV nephropathy; see Chapter 56), dehydration, therapeutic agents, opportunistic infections, or coexistent infections (HCV) and intravenous drug abuse (Fig. 66.13).²⁶ Prerenal azotemia is the most common cause of AKI in patients with HIV infection, and ATN caused by hypotension or nephrotoxic medications is also common. A hemolytic-uremic syndrome has also been described in HIV infection. In view of the wide differential diagnosis, renal biopsy should be considered when AKI does not respond to supportive measures. In the HIV-infected intravenous drug user, AKI may be due to concomitant HCV infection associated with membranoproliferative glomerulonephritis or to complications related to intravenous drug use (most notably endocarditis-associated renal disease or rhabdomyolysis).

Drug Therapy

Protease inhibitors may cause AKI in patients with HIV infection (see Chapter 56). This commonly occurs with indinavir, which can cause intratubular crystal obstruction or obstructing renal calculi, but it has also been reported with ritonavir. Reverse transcriptase inhibitors may also produce AKI. Tenofovir, a nucleoside reverse transcriptase inhibitor, is now commonly used in HAART regimens and is nephrotoxic.²⁷ Tenofovir toxicity initially is manifested as Fanconi syndrome and progresses to ATN. Several of the antiretroviral agents used to treat HIV

Causes of Acute Kidney Injury in Patients with HIV Infection	
Prerenal	Diarrhea, nausea and vomiting, cirrhosis and hepatorenal syndrome, sepsis
Vascular	Thrombotic microangiopathy
Glomerular	Immune complex glomerulonephritis (MPGN secondary to hepatitis C virus, postinfectious glomerulonephritis), HIVAN
Acute tubular necrosis	Sepsis, hypotension, nephrotoxins (aminoglycosides, amphotericin, acyclovir, cidofovir, tenofovir, pentamidine), rhabdomyolysis
Acute interstitial nephritis	Drug induced (cotrimoxazole, rifampicin, foscarnet, nevirapine), CMV infection, DILS
Drug-induced intratubular obstruction	Sulfadiazine, indinavir, foscarnet, acyclovir
Postrenal obstruction	Stones, tuberculosis, fungal ball, tumor
Associated with IV drug use	Sepsis, endocarditis, heroin-associated nephropathy (FSGS), rhabdomyolysis

Figure 66.13 Causes of acute kidney injury in patients with HIV infection. CMV, cytomegalovirus; DILS, diffuse infiltrative lymphocytosis syndrome; FSGS, focal segmental glomerulosclerosis; HIVAN, HIV-associated nephropathy; MPGN, membranoproliferative glomerulonephritis.

infection can cause acute interstitial nephritis, including indinavir, atazanavir, and abacavir.

Treatment of opportunistic infections often requires the use of potentially nephrotoxic drugs, such as aminoglycosides and amphotericin. *Pneumocystis* species infection may be treated with high-dose cotrimoxazole (acute interstitial nephritis or intratubular crystal obstruction) or pentamidine (ATN in 25% of cases). Resistant cytomegalovirus infection may require foscarnet therapy (acute interstitial nephritis or intratubular crystal obstruction).

Acute Kidney Injury in the Cancer Patient

Patients with cancer are prone to AKI as a consequence of both their underlying disease and its treatment, and AKI may occur in up to 50% of critically ill cancer patients.²⁸ There is also a high incidence of prerenal azotemia in this group of patients due to the high frequency of nausea, vomiting, and diarrhea (Fig. 66.14). More specific causes of AKI are noted in the following sections.

Tumor Lysis Syndrome

Necrosis of large numbers of tumor cells, typically after chemotherapy, may release large amounts of nephrotoxic intracellular contents (uric acid, phosphate, xanthine) into the circulation.²⁹ It usually occurs after treatment of lymphomas (particularly Burkitt's) and leukemias, but it may occur spontaneously in patients with rapidly dividing tumor cells. It has also been seen with solid tumors. Rarely, a spontaneous form of tumor lysis syndrome occurs in rapidly growing tumors that outstrip their blood supply.

In earlier days, hyperuricemia resulted in acute urate nephropathy due to intratubular crystal obstruction and interstitial nephritis, but this is now less common because of the prophylactic use of allopurinol before chemotherapy. Other intracellular components are now more commonly involved, such as phosphate release with the precipitation of calcium phosphate in the tubules.

Causes of Acute Kidney Injury in Patients with Cancer	
Prerenal	Nausea and vomiting, hypercalcemia, cardiomyopathy secondary to chemotherapy
Vascular	Thrombotic microangiopathy (adenocarcinoma of stomach, pancreas, prostate; radiation nephropathy), renal vein thrombosis secondary to hypercoagulability, disseminated intravascular coagulation (acute promyelocytic leukemia)
Glomerular	Rapidly progressive glomerulonephritis
Acute tubular necrosis	Sepsis and antibiotic nephrotoxicity, hypercalcemia
Malignant infiltration	Lymphoma, acute lymphoblastic leukemia
Intraluminal obstruction	Tumor lysis syndrome, cast nephropathy
Postrenal obstruction	Transitional cell carcinoma of the ureters/bladder, extrinsic ureteral compression (tumor, nodes, retroperitoneal fibrosis)
Chemotherapeutic agents	
Tubular toxicity	Cisplatin, ifosfamide, plicamycin (mithramycin); 5-fluorouracil, thioguanine (6-thioguanine), cytarabine
Thrombotic microangiopathy	Mitomycin C, bleomycin, cisplatin, calcineurin inhibitors
Other mechanisms	Capillary leak syndrome (IL-2 therapy), acute interstitial nephritis (interferon- α), intraluminal obstruction (methotrexate)

Figure 66.14 Causes of acute kidney injury in patients with cancer. IL-2, interleukin-2.

The AKI is typically oligoanuric, and the condition should be suspected in patients with high lactate dehydrogenase levels suggestive of massive cell lysis. Markedly elevated phosphate and urate levels may also be found. Hyperkalemia may be prominent and life-threatening.

Preventive measures include the use of high-dose allopurinol (600 to 900 mg/day) started 2 to 3 days before chemotherapy and either oral or intravenous fluid loading to ensure a urine output of more than 2.5 L/day. Urine alkalization is of less benefit than merely maintaining a high urine flow with saline, and it may promote tubular calcium phosphate deposition. However, it should be considered when serum uric acid levels are elevated (>12 mg/dL [$714 \mu\text{mol/L}$]) or urinary uric acid crystals are present. Recombinant uricase (rasburicase) is effective in lowering serum uric acid levels (to <1 mg/dL in 24 hours) and should be considered for prophylaxis in high-risk patients.

Once the patient develops AKI with hyperuricemia, rasburicase, which lowers uric acid much more effectively than dialysis does, should be considered. It can lower uric acid levels within hours and also is effective in patients with impaired renal function. If this is not available or the patient is markedly hyperphosphatemic, early dialysis should be considered to remove these potential causes of further renal damage. Because phosphate is less well removed by dialysis than urate is, frequent (every 12 to 24 hours) or prolonged treatments should be considered.

Hypercalcemia

Volume depletion secondary to hypercalcemia-induced nausea and vomiting may cause AKI, which may be exacerbated by hypercalcemia-induced nephrogenic diabetes insipidus. Other hypercalcemia-associated factors that may contribute to AKI include direct intrarenal vasoconstriction, acute interstitial nephritis, and intratubular obstruction.

Renal Infiltration

Direct infiltration of the kidneys by tumor is not uncommon; however, this rarely results in renal failure. AKI may be seen with slow-growing lymphomas or leukemias, when the patient presents with nonoliguric AKI, a benign urine sediment, and enlarged kidneys on ultrasound scan. Renal function may improve, depending on the responsiveness of the tumor to treatment. Tumor-related urinary tract obstruction should also be considered.

Chemotherapeutic Agents

Cisplatin is commonly associated with a nonoliguric renal impairment.³⁰ Nephrotoxic injury affects both the proximal and distal nephron and clinically may be associated with magnesium wasting, impaired urinary concentration, and rarely salt wasting with volume depletion. Chloride ions in the *cis* position on the molecule may be replaced by water, releasing toxic hydroxyl radicals. Prophylaxis against nephrotoxicity includes volume loading, possibly with hypertonic saline, and the use of the antioxidant amifostine as a thiol donor. The alternative agent carboplatin appears to be less nephrotoxic. Once renal impairment is present, recovery may be poor, and magnesium wasting may persist.

Ifosfamide is a cyclophosphamide analogue with a nephrotoxic metabolite, chloroacetaldehyde. AKI is usually mild, although proximal tubular dysfunction (Fanconi syndrome) and hypokalemia may be prominent.

High-dose intravenous methotrexate is also nephrotoxic, possibly because of precipitation of the drug within the renal tubules and direct toxicity to the renal epithelial cells.

Cytosine arabinoside and 5-fluorouracil may increase the likelihood of AKI when they are included in multidrug regimens. Both agents, for example, are associated with AKI when they are given in combination with cisplatin.

Bone Marrow Transplant

AKI is common in patients undergoing hematopoietic cell transplantation (HCT), and some degree of renal dysfunction can be seen in more than 90% of the patients who undergo allogeneic HCT. These patients often have multiple risk factors for the development of AKI, including reactions to the infused hematopoietic cells, infections, nephrotoxic drugs, and dehydration. AKI is less common after autologous HCT, probably because the patients do not require chronic immunosuppression with nephrotoxic agents.

Acute Kidney Injury in the Tropics

Emmanuel A. Burdmann, Vivekanand Jha, Visith Sitprija

In tropical countries, the epidemiologic pattern of acute kidney injury (AKI) encountered in tertiary hospitals in densely inhabited cities will be similar to that in developed nontropical countries (see Chapter 66). In contrast, in the same cities and in the countryside, particular causes of AKI, such as malaria, yellow fever, hemorrhagic dengue, and leptospirosis, may be found, frequently affecting young and previously healthy individuals. Septic abortion is no longer a relevant cause of AKI in the developed world, but it remains a significant medical problem in some tropical countries. There are regions in Asia where venomous snakebite is the leading cause of community-acquired AKI. Rupture of the ecological balance by humans has induced particular causes of renal injury in the tropics, like accidents with the Africanized bee or *Lonomia* genus caterpillars. Natural medicines prescribed by traditional healers are an important cause of AKI in Africa and Asia.

In this chapter, specific causes of AKI, such as venomous snakebite, arthropod venom, and herbal and natural medicines, are discussed. Some of the most important infectious diseases causing AKI in the tropics (malaria, leptospirosis, and yellow fever) are reviewed.

SNAKEBITES

Snakebite is an occupational hazard in the rural tropics. Renal injury may develop after bites by several kinds of venomous snakes, such as Russell's viper, saw-scaled viper, puff adder, rattlesnake, tiger snake, green pit viper, *Bothrops*, *Lachesis*, *Crotalus*, boomslang, gwardar, dugite, *Hypnale*, *Cryptophis*, and sea snakes.¹⁻³ AKI is more frequent after Russell's viper (Fig. 67.1), *Bothrops*, or *Crotalus* bites, with incidences ranging from 10% to 32%.¹⁻³ The prevalence is higher in children, probably because of the higher venom dose in relation to the body size.⁴

Clinical Features

Manifestations depend on the nature of the venom and the injected dose. Pain, swelling, blister formation, ecchymosis of the bitten part, and tissue necrosis are frequent in Russell's viper and *Bothrops* bites (Figs. 67.2 and 67.3). The most common systemic manifestation in accidents by these snakes is coagulation abnormalities leading to bleeding diathesis (Fig. 67.3). Muscle paralysis may occur with *Crotalus* bites and rhabdomyolysis after bites by sea snakes and *Crotalus*. Renal injury develops within a few hours to as late as 96 hours after the bite. Cola-colored urine is noted in those with hemolysis or rhabdomyolysis. AKI is usually oliguric and catabolic, with rapidly rising levels of blood urea nitrogen, serum creatinine, and potassium. Oliguria generally lasts for

1 to 2 weeks, and its persistence suggests the likelihood of acute cortical necrosis.¹⁻⁴

Investigations may show evidence of hemolysis (elevated free plasma hemoglobin, lactate dehydrogenase, and reduced haptoglobin) along with hypofibrinogenemia; reduced factors V, X, and XIIIa and protein C and antithrombin C; and elevated fibrin degradation products. Rhabdomyolysis may be indicated by raised creatine kinase. Other findings include leukocytosis and elevated hematocrit due to hemoconcentration.¹⁻⁴

Pathology

In gross appearance, the kidneys may show petechial hemorrhages. Light microscopy usually discloses acute tubular cell injury ranging from mild changes to overt tubular necrosis, with hyaline or pigment casts, variable degrees of interstitial edema and cell infiltration, and scattered hemorrhages. Mesangiolysis is also common (especially with crotalid envenomation). Blood vessels may show fibrin thrombi. Electron microscopic findings include dense intracytoplasmic bodies representing degenerated organelles in the proximal tubules and electron-dense mesangial deposits. Less common findings are acute interstitial nephritis, necrotizing vasculitis, and proliferative and crescentic immune complex glomerulonephritis. Acute cortical necrosis is seen in about 20% to 25% of cases after Russell's viper and *Echis carinatus* bites and has been described after *Bothrops* accidents.¹⁻³

Pathogenesis

Snake venom is a complex mixture of enzymes, toxins, and peptides. Renal injury may develop as a result of direct nephrotoxicity, renal vasoconstriction, hypovolemia, hemolysis, altered fibrinolysis, myoglobinuria, or disseminated intravascular coagulation.¹⁻⁴ Experimental studies have shown evidence of tubular injury manifested by increased excretion of tubular enzymes, altered fractional sodium excretion, and acute tubular necrosis.¹⁻⁵ Other changes including mesangiolysis, disrupted integrity of the cellular junctions, proteolysis of extracellular matrix, lysis of vessel wall (leading to mesangiolysis), and alterations in function of enzymes vital to cellular integrity have been noted.¹⁻³ Hypovolemia and hypotension secondary to bleeding, third spacing of fluids, and depression of the medullary vasomotor center or the myocardium may play a role.^{2,3}

Management

The basic therapeutic approach is the same as that for AKI due to any cause. Key steps for reducing morbidity and mortality

Figure 67.1 Russell's viper snake. This large snake is an important cause of venomous snakebite-induced AKI in Asia.

Figure 67.2 Necrotic finger injury after *Bothrops* snakebite. (Courtesy Carlos A. C. Mendes, São José do Rio Preto, Brazil.)

Figure 67.3 Hemorrhagic blister developing a few hours after *Bothrops* snakebite. (Courtesy Carlos A. C. Mendes, São José do Rio Preto, Brazil.)

include early administration of antivenom, appropriate volume replacement, maintenance of good urine flow, urinary alkalization in cases of rhabdomyolysis, correction of electrolyte imbalance, administration of tetanus immune globulin, and treatment of infections. Antivenom should be initiated in adequate amounts and by the appropriate route as soon as signs of local or systemic envenomation are noted.¹⁻⁵ Knowledge of the offending snake species allows administration of specific monovalent antivenom. Immunodiagnostic techniques can help in identification of venom antigen but are time-consuming. The overall mortality rate may reach 30%.¹⁻⁵ The prognosis is favorable in patients receiving early and adequate doses of antivenom. Renal functional recovery is usually complete except in those with acute cortical necrosis, who may be left with varying degrees of dysfunction, depending on the amount of viable parenchyma.

ARTHROPODS

Poisonous arthropods such as bees, wasps, caterpillars, and spiders may cause AKI. Patients receiving hundreds of simultaneous bee stings frequently have a multifaceted clinical picture, which may include intravascular hemolysis, rhabdomyolysis, low platelet count, coagulation disorders and bleeding, cardiovascular injury, hepatic injury, pulmonary injury, and AKI. In the same way, AKI can follow accidents with multiple wasp, yellow jacket, or hornet stings.^{2,6} The mechanisms leading to renal injury are likely to be direct venom nephrotoxicity, intrarenal vasoconstriction, hemoglobinuria, myoglobinuria, and hypotension.⁷ Renal histology usually shows acute tubular necrosis.^{2,6,7}

Accidents with caterpillars of the genus *Lonomia* produce severe hemorrhagic disorders. The venom induces a complex hemorrhagic diathesis with both fibrinolytic and disseminated intravascular coagulation-like activity. Severe and prolonged AKI with renal histology suggesting ischemic injury has been reported after accidents with *Lonomia obliqua* (Fig. 67.4), and some patients did not recover renal function. Availability of *Lonomia* antivenom has led to an apparent decrease in the number of severe cases in Brazil.^{6,8}

Spiders of the genus *Loxosceles* (Fig. 67.5) may induce late local necrosis at the bite site (Fig. 67.6), intravascular hemolysis, rhabdomyolysis, coagulation system changes, and acute renal injury. Even patients with mild cutaneous lesions may develop severe hemolysis and AKI, which is the main cause of death after these accidents.^{6,9}

NATURAL MEDICINES

Herbs and indigenous remedies are used extensively in poor societies living in the tropics. About 50% to 80% of the population in Africa and China depends on traditional medicine for primary health care. Poisoning with traditional medicines is an important cause of mortality in sub-Saharan Africa. Herbalists and faith healers use unknown ingredients to prepare these medicines, which are not tested for efficacy and safety.^{2,10,11}

AKI has been described in association with several of these natural remedies (see also Chapter 74). An accurate assessment of their contribution to AKI is rendered difficult by the failure of physicians to elicit a history because of ignorance or denial by the patients due to fear of stigmatization or social pressures. It is often difficult to discount the contribution of the original illness to the AKI.¹⁰

About 25% to 35% of all AKI due to medical causes in various African hospitals is related to herbal remedies. Accidental oral ingestion of the hair dye paraphenylenediamine is responsible for about 10% of all AKI cases in Morocco. The natural compounds more frequently associated with AKI are impila (*Callilepis laureola*), djenkol beans (*Pithecolobium*), mushrooms (genera *Amanita*, *Galerina*, *Cortinarius*, and *Inocybe*), cape aloe, and raw carp bile.^{10,11} In addition, single case reports of other natural medicines inducing AKI can be found (Fig. 67.7).^{10,11}

Kidney injury may be either the sole manifestation or part of a multisystem involvement that includes acid-base disturbances, liver failure, neurologic abnormalities, disseminated intravascular coagulation, or respiratory failure. Management of AKI is usually supportive (see Chapter 69) and includes volume replacement and correction of metabolic abnormalities. Dialytic support is given for usual indications (see Chapter 70). About 60% of all herbal remedy–related AKI cases need dialysis, with 25% to 75% mortality. Charcoal hemoperfusion is effective in clearing α -amanitin from the circulation in those with poisoning due to *Amanita* mushrooms.¹⁰

Pathogenesis of Natural Medicine–Induced Acute Kidney Injury

Several factors affect the toxicity and likelihood of kidney injury. Adulteration of indigenous medicines is common (see Chapter 74). Incorrect identification by inexperienced personnel may lead

Figure 67.6 Local necrotic injury in the left leg of a female patient after *Loxosceles* bite. **A**, At 4 days after the bite. **B**, At 60 days after the bite. **C**, At 3 months after the bite. (Courtesy Carlos A. C. Mendes, São José do Rio Preto, Brazil.)

Traditional Remedies Associated with AKI in the Tropics				
Plant	Reported from	Active molecule	Nature of kidney injury	Other manifestations
<i>Averrhoa carambola</i> (star fruit)	Hong Kong, Taiwan	Oxalate	Intratubular precipitation of oxalate crystals	Vomiting
<i>Catha edulis</i> (khat leaf)	East Africa, Arab peninsula	S-Cathinone, ephedrine	ATN	Hepatotoxicity
CKLS*	Atlanta, Georgia (USA)	Multiple toxins	AIN, hematuria	Diarrhea, abdominal pain
<i>Cleistanthus collinus</i> (Oduvan)	India	Cleistanthin A and B, collinusin, diphyllyne	AKI	Hypotension, hypokalemia, arrhythmia
<i>Colchicum autumnale</i> (meadow saffron)	Turkey	Colchicine	ATN	Hemorrhagic gastroenteritis, muscle paralysis, respiratory failure
<i>Crotalaria laburnifolia</i> (Bird flower)	Zimbabwe, Sri Lanka	Pyrrolizidine alkaloids	ATN, HRS	Hepatic veno-occlusive disease, pulmonary injury, thrombocytopenia
<i>Cupressus funebris</i> Endl (mourning cypress)	Taiwan	Flavonoid	ATN, AIN	AHF, hemolytic anemia, thrombocytopenia
<i>Dioscorea quartiniana</i> (yam)	Africa, Asia	Dioscorine, dioscin	ATN	Convulsions
<i>Euphorbia metabelensis</i> (spurge)	Zimbabwe	Irritant chemicals in plant latex	ATN	Thrombocytopenia
<i>Glycyrrhiza glabrata</i> (licorice)	Several countries	Glycyrrhizic acid	ATN	Rhabdomyolysis, hypokalemia, hypertension, cardiac arrhythmia
<i>Larrea tridentate</i> (chaparral)	Chile, South Africa	Nordihydroguaiaretic acid, S-quinone	Renal cysts, renal cell carcinoma	Hepatic failure
<i>Lytta vesicatoria</i> (Spanish fly)	South Africa, USA	Cantharidin	ATN, hematuria	GI symptoms, neuromuscular paralysis
<i>Propolis</i>	Brazil, Taiwan	Unknown	AIN	Contact dermatitis
<i>Rhizoma rhei</i>	Hong Kong	Anthraquinones (emodin, aloe emodin)	AIN	None
<i>Securidacea longepedunculata</i> (violet tree, wild wisteria)	Congo, Zambia, Zimbabwe	Methylsalicylate, securinine, saponins	ATN	Vomiting, diarrhea
<i>Sutherlandia frutesces</i> (cancer brush), <i>Dodonaea angustifolia</i>	South Africa	Unknown	AIN	Pulmonary embolism
Takaout roumia	Morocco, Sudan	Paraphenylenediamine	ATN	Rhabdomyolysis
<i>Taxus celebica</i> (Chinese yew)	Asia	Flavonoid	ATN, AIN	Hepatitis, hemolysis, DIC
<i>Thevetia peruviana</i> (yellow oleander)	India, Sri Lanka	Cardiac glycosides	ATN, mesangiolytic	Liver failure, cardiac arrhythmias
<i>Tripterygium wilfordii</i> Hook F (thunder god vine)	Taiwan	Triptolide	ATN	Diarrhea, shock

to substitution of a medicinal plant with a toxic one. An example is the substitution of Takaout el badia, a hair dye made from *Tamarix orientalis* seeds, with the toxic Takaout roumia (paraphenylenediamine). Finally, incorrect methods of preparation or consumption cause nephrotoxicity. Examples include consumption of improperly cooked djenkol beans, star fruit, or yam and failure to ingest impila in the prescribed way (with sufficient water, followed by regurgitation soon after consumption). Indirect mechanisms include interaction with metabolism of conventional drugs. St. John's wort (*Hypericum perforatum*) decreases plasma levels of drugs that are metabolized by the cytochrome P-450 enzyme system. In kidney transplant recipients, this interaction can lower levels of calcineurin inhibitors and precipitate AKI due to allograft rejection. Concomitant administration of other nephrotoxic medicines can also potentiate herbal nephrotoxicity.^{10,11}

MALARIA

Malaria is caused by four species of malarial *Plasmodium* parasites: *falciparum*, *vivax*, *malariae*, and *ovale*. It has been estimated that globally, malaria afflicts nearly 250 million patients annually with one million deaths, mostly of children with *P. falciparum*.¹² The contribution of malaria as the cause of AKI among different geographic areas ranges from 2% to 39%. The incidence of AKI in *P. falciparum*-induced malaria can be as high as 60%. AKI is uncommon in the other forms of malaria but may be observed in complicated cases of *P. vivax* infection.¹³ In this chapter, we focus on falciparum malaria-associated AKI. Glomerular disease associated with malaria infection is discussed in Chapter 55.

Pathophysiology

The inherent characteristics of each species of malarial parasite are important determinants in malaria pathogenesis. *P. vivax* and *P. ovale* infect young erythrocytes, and *P. malariae* infects aging cells. *P. falciparum* infects erythrocytes of all ages, producing a higher number of merozoites (Fig. 67.8). Heavy parasitemia is therefore commonly observed in falciparum malaria, creating adverse effects on microcirculation. The pathophysiologic process of malaria involves membrane changes, inflammation, and hemodynamic alterations.¹⁴ *Plasmodium* parasites primarily infect erythrocytes with secondary effects on the microcirculation and immune system. Parasitized erythrocytes are integral to the pathophysiologic process of the disease through decreased erythrocyte deformability and sequestration, knobs and rosette formation, cytoadherence, and changes in membrane transport and permeability. Interestingly, nonparasitized erythrocytes also have decreased deformability. The presence of blebs on parasitized erythrocyte membranes and cytoadherence between parasitized erythrocytes and vascular endothelial cells are characteristic of falciparum malaria. Other forms of *Plasmodium* do not have this property. Similar to other infectious diseases, several proinflammatory cytokines and vasoactive mediators are released. Hemodynamic changes in malaria are similar to those of bacterial sepsis: decreased systemic vascular resistance, increased cardiac output, and increased renal vascular resistance. The initial hypervolemia is followed by hypovolemia and decreased cardiac output, with renal blood flow and glomerular filtration rate decrease. Increased blood viscosity, intravascular coagulation, hemolysis, rhabdomyolysis, jaundice, fever, lactic acidosis, complement activation, and reactive oxygen species further compromise renal blood flow. Activation of poly(ADP-ribose)

Figure 67.8 Ring form and merozoites of *Plasmodium falciparum* in infected erythrocytes.

Figure 67.9 Acute tubular necrosis in falciparum malaria.

polymerase by peroxynitrite and free radicals decreases oxygen utilization. AKI in malaria is therefore ischemic and hypoxic in origin and usually occurs in the patient with heavy parasitemia or intravascular hemolysis or rhabdomyolysis.^{13,14}

Immune responses in malaria involve both Th1 and Th2 activation. Immune complex glomerulonephritis is usually observed, with granular deposition of C3, IgM, and malarial antigen in the mesangial area and *in situ* immune complex deposition. Tubular changes vary from cloudy swelling to tubular degeneration with tubulorrhexis in the patient with AKI (Fig. 67.9). Bile and hemoglobin casts and Tamm-Horsfall protein are present in the tubular lumen. Interstitial mononuclear infiltration and edema can be observed. Malarial antigens are occasionally seen along the glomerular endothelium and medullary capillaries. Adhesion molecules and proinflammatory cytokines are overexpressed in the vascular endothelium and proximal tubules.^{13,14}

Clinical Manifestations

Malarial AKI affects predominantly nonimmune adults, mostly infected by *P. falciparum*. Constitutional symptoms include fever, chills, headache, and prostration. Jaundice may be present. The urinalysis usually shows few erythrocytes, leukocytes, and granular casts and mild proteinuria (often less than 1 g/24 h). Hemoglobinuria is noted in the patient with intravascular hemolysis,

frequently associated with glucose-6-phosphate dehydrogenase deficiency. Rhabdomyolysis with myoglobinuria has been observed. Fluid and electrolyte changes are common in malaria.¹³⁻¹⁵ Hyponatremia, usually asymptomatic, is observed in 67% of patients and is related to the severity of malaria. Decreased response to water load is seen in 20% of hyponatremic patients. Fluid should be administered cautiously in hyponatremic patients to avoid fluid overload. Hyponatremia resolves within a few days after antimalarial treatment. The causes of hyponatremia are multiple, including increased antidiuretic hormone with water retention, intracellular shift of sodium due to decreased $\text{Na}^+\text{K}^+\text{-ATPase}$ activity, and sodium depletion. Hypernatremia is uncommon and when present indicates hypothalamic lesions with diabetes insipidus, being associated with unfavorable prognosis. Hypokalemia due to respiratory alkalosis occurs in 20% to 40% of the patients. Hyperkalemia is observed in patients with intravascular hemolysis, rhabdomyolysis, or AKI. Hypocalcemia with prolonged QTc interval occurs in 45% of severe malaria, is transient, and resolves when infection is controlled.¹⁵ Decreased activities of $\text{Na}^+\text{K}^+\text{-ATPase}$, $\text{Ca}^{2+}\text{-ATPase}$, and parathyroid hormone are considered the main causes. Hypophosphatemia secondary to respiratory alkalosis is observed in 6% to 30% of the patients. The clinical significance of both hypocalcemia and hypophosphatemia is unknown. Hypomagnesemia is seen in 30% of patients.¹⁵

AKI is characterized by a rapid increase in blood urea nitrogen and serum creatinine and is often associated with cholestatic jaundice. Hepatocellular jaundice may be observed with hypotension and secondary hepatic injury. Severe acidosis, hypoglycemia, and central nervous system symptoms can be observed. The duration of AKI ranges from one to several weeks and is oliguric in 60% of the patients. Quinine and artesunate are the antimalarial agents of choice. Early and frequent dialysis (hemodialysis or peritoneal dialysis) is lifesaving.¹³ Continuous venovenous hemofiltration yields good results in patients with multiorgan involvement, especially those with pulmonary edema or acute respiratory distress syndrome.¹³ Exchange blood transfusion and erythrocytapheresis are adjunctive for the patient with heavy parasitemia.¹⁶ The mortality rate of malarial AKI ranges from 10% to 50%. Multiple organ involvement carries poor prognosis. The use of dopamine with furosemide in attenuating the progress of mild uncomplicated malarial renal injury has been successful.¹⁴ This is in contrast to the experience in other causes of AKI (see Chapter 69) and requires larger randomized controlled studies to be validated.

LEPTOSPIROSIS

Leptospirosis, a worldwide zoonosis, is caused by *Leptospira* genus spirochetes. There are more than 200 pathogenic serovars of *Leptospira* occurring in tropical and subtropical areas, which makes this infection a major public health burden. In fact, the World Health Organization included leptospirosis as a reemerging infectious disease in both developed and developing areas. Wild and domestic mammals, such as rodents, dogs, pigs, cattle, and horses, are the typical vectors for leptospirosis. The infection is transmitted to humans through animal urine.^{2,17,18}

Human leptospirosis is endemic in many tropical countries and usually reaches epidemic levels after either higher rainfall periods with flooding or natural disasters, such as hurricanes. Human cases range from 10 to 100 per 100,000/year in the humid tropics. This figure rises during outbreaks and in high-risk groups. Epidemic leptospirosis was recently reported in

Nicaragua and Puerto Rico after hurricane strikes and in Brazil after summer floods. Some studies showed a high seroprevalence of anti-*Leptospira* antibodies in the general asymptomatic population, ranging from 18% to 33%. With use of polymerase chain reaction assay, 29% of wild small animals in the Peruvian Amazon were found to be infected by leptospires.^{2,17,18}

Leptospira interrogans, the only parasitic species, is mobile, aerobic, and unstained by the Gram method. Its endotoxins affect the tubulointerstitial cells. Glomerular changes are usually not relevant. The bacterial outer membrane contains lipopolysaccharide, cytotoxic glycolipoprotein, and lipoproteins (especially LipL 32, which is immunogenic and a new hope for a universal leptospiral human vaccine). As leptospires have special tropism for kidneys, the effect of glycolipoprotein on tubular $\text{Na}^+\text{K}^+\text{-ATPase}$ activity is potentially involved in both the AKI cellular pathophysiologic process¹⁹ and the paradoxical hypokalemia frequently seen in these patients.^{2,17,18} High serum free fatty acids, mainly oleic acids (C18:1), are also potentially implicated in pulmonary hemorrhagic manifestations of the acute respiratory distress syndrome associated with this disease.²⁰

Renal involvement is almost universal in leptospirosis but becomes relevant in Weil's disease, which represents the most severe form of the disease. Weil's syndrome is characterized by multiorgan involvement, with diffuse alveolar hemorrhage, pulmonary edema, acute respiratory distress syndrome, or a combination of these features, accompanied by AKI; it has a 50% mortality rate. The incidence of leptospirosis-associated AKI varies from less than 10% to more than 60% of these patients. AKI is typically nonoliguric and associated with hypokalemia.^{2,17,18,21} Tubular changes characterized by high urinary fractional excretion of sodium and potassium precede glomerular filtration rate decrease, which could explain the high prevalence of hypokalemia. Antibiotic treatment is efficient in the early and late-severe phases.¹⁷ Treatment recommendations include a high dialysis dose, conservative fluid intake, and approaches to minimize lung injury, such as low tidal volume and high positive end-expiratory pressure when artificial ventilation is required.^{17,21}

HEMORRHAGIC FEVERS

Viral hemorrhagic fevers (VHF) are caused by RNA viruses of four different families (Flaviviridae, Arenaviridae, Bunyaviridae, and Filoviridae). They can be acquired by infected arthropod bite (dengue, Rift Valley, yellow fever, and the Crimean-Congo viruses) or by inhalation of infected rodent excreta particles (Lassa, Junin, Machupo, and Hantaan viruses). The clinical picture of VHF is characterized by fever, malaise, increased vascular permeability, and coagulation abnormalities that may lead to bleeding. AKI is an unusual complication of these diseases but has been reported in association with several forms of VHF.^{2,18,22} Dengue and yellow fever are the most prevalent forms of VHF in the tropical regions.²²

Dengue Fever

Dengue is an acute febrile disease caused by an arbovirus, transmitted primarily by mosquitoes, with a benign evolution in most cases. The main dengue vector is the *Aedes aegypti* female mosquito. It is currently the most important urban arboviral disease, affecting millions of people on all continents except Europe. It is more prevalent in tropical and subtropical areas where the environment is favorable for the mosquito's development. It is

estimated that half the world's population lives in areas at risk for dengue disease, and about 50 to 100 million cases occur annually. Several factors account for the rising incidence and widespread distribution of dengue, such as climate changes (global warming, intensity and duration of rain season, hurricanes), ecosystem modifications, demographic increases, uncontrolled and unplanned urbanization, and migration of people.²²

There are four serotypes of dengue flavivirus (DEN1 to DEN4). They are antigenically related, but one serotype does not confer enduring immunity to another. The introduction of a new serotype in a determinate area accounts for the occurrence of epidemics and the hemorrhagic fever dengue form, which is a more severe form of the disease that may be lethal.²²

Dengue virus infection may be manifested as undifferentiated fever, dengue fever, dengue hemorrhagic fever (DHF), or dengue shock syndrome (DSS). Common clinical manifestations of dengue fever are high fever, myalgia, arthralgia, retro-ocular pain, headache, anorexia, nausea, vomiting, and a cutaneous rash similar to that of measles or rubella. DHF and DSS are severe forms of the disease characterized by fever, hemorrhagic phenomena, thrombocytopenia, evidence of plasma leakage (increased hematocrit, pleural effusion, ascites, and hypoalbuminemia), mental disorientation, breath shortness, tachycardia, shock, and death.

Renal involvement in dengue includes glomerulonephritis, AKI, and hemolytic-uremic syndrome. Dengue-induced AKI is usually associated with shock, hemolysis, or rhabdomyolysis,²² but it may occur without any of these triggering factors.²³ There is no specific treatment of dengue fever. Therapy is mostly supportive, avoiding the use of aspirin and nonsteroidal anti-inflammatory drugs.

Yellow Fever

Yellow fever is a noncontagious infectious disease that is endemic in tropical Africa, South America, and Panama. The yellow fever virus is part of the *Flavivirus* genus (Flaviviridae family).²²

Yellow fever is transmitted to humans by blood-eating insect bites, especially by the *Aedes* and *Haemagogus* genera. There are sylvatic and urban cycles. The sylvatic cycle affects sporadic individuals who come into contact with the vectors in performing economic or recreational activities in infested forests. The urban cycle is characterized by virus transmission through *A. aegypti* to individuals living in urban areas. The urban cycle was eliminated in the Americas from the 1940s to the 1950s, but its resurgence was recently documented in Bolivia. The movement of infected individuals when they are viremic to cities with high vector populations can potentially generate explosive urban epidemics affecting thousands of nonvaccinated people.²⁴ Interestingly, there is no evidence of yellow fever in Asia, despite an extensive presence of vectors. It is possible that the hyperendemicity of dengue in southwest Asia has afforded protection due to cross-reactive antibodies. This mechanism might also explain why urban yellow fever has not reemerged in Brazil after the reintroduction and spread of the *Aedes* vector and the occurrence of a large number of cases of dengue in the last 20 years.²²

The diagnosis of yellow fever is made by measuring serum-specific IgM, by viral isolation in insect or mammal cells, and by molecular methods such as reverse transcription-polymerase chain reaction. The most specific pathologic finding of yellow fever is liver injury with formation of Councilman corpuscles. Both viral RNA and antigens are found in these cells, suggesting a direct viral cytopathy.^{22,25}

Clinically, yellow fever infection might be asymptomatic, cause moderate febrile disease, or be severe, causing hemorrhagic fever, liver failure, AKI, and death. The majority of the patients (85%) fully recover after 3 to 4 days and become permanently immunized against the disease. About 20% develop the severe form, with mortality up to 50% of the cases.²²

After 3 to 6 days of incubation, the clinical picture of yellow fever starts abruptly with high fever, chills, anorexia, myalgia, headache, vomiting, and bradycardia. Hemorrhagic manifestations may occur. There is then a remission period with symptom improvement, and mild cases do not have any further manifestations. In the severe forms, fever comes back, followed by vomiting, epigastric pain, and jaundice, the so-called intoxication phase. There are large increases in transaminases and bilirubin. Leukopenia and ST-segment abnormalities are also found. Hemorrhagic events, such as hematemesis, melena, petechiae, bruises, mucosal bleeding, and metrorrhagia in women, can occur in association with hepatic damage and consumptive coagulopathy. Microcirculatory thrombosis, disseminated intravascular coagulation, tissue anoxia, oliguria, and shock may follow.²²

Yellow fever-associated renal injury is usually observed after 5 days of disease in the severe forms; it may evolve to anuria and acute tubular necrosis, with increased mortality. In Africa, AKI is observed earlier and in the absence of jaundice or liver abnormalities, with higher mortality. The mechanisms of kidney injury are poorly understood. In experimental studies performed in Rhesus monkeys in the 1980s, the renal disorder appeared to be prerenal until the last 24 hours of life of the animal. The final phase was characterized by marked oliguria, azotemia, and acidosis, with severe tubular necrosis seen at autopsy. In humans, an eosinophilic degeneration of the renal epithelial cells was described. Viral antigen identification in human renal tissue and after experimental infection in animals suggests a direct action of the virus on renal tissue.²²

Diagnosis and Clinical Evaluation of Acute Kidney Injury

Li Yang, Joseph V. Bonventre

Acute kidney injury (AKI) occurs in response to a large number of pathophysiologic influences and is characterized by damage to one or more parts of the nephron with adverse functional consequences (see Chapters 66 and 68). Depending on the severity and duration of the kidney dysfunction, the clinical manifestations of AKI are accompanied by metabolic disturbances such as metabolic acidosis and hyperkalemia, abnormal body fluid balance, and effects on other organ systems. AKI can also be asymptomatic, which can result in the absence of a diagnosis or a significant delay in the diagnosis. In this case, asymptomatic AKI will be found on routine biochemical screening of hospitalized patients, revealing an increase in the concentration of blood urea nitrogen (BUN) and creatinine. It is increasingly recognized that AKI is much more common in the population of hospitalized patients and that even milder forms of dysfunction may have important consequences. Furthermore, there is emerging evidence that AKI episodes can lead to chronic kidney disease (CKD), accelerate the progression to end-stage renal disease (ESRD), and contribute to higher long-term mortality risk.^{1,2}

AKI is a heterogeneous condition with a plethora of causes, which are generally categorized into prerenal, renal, and postrenal (see Chapter 66). Early detection and identification of the etiology of AKI are critical for designing and implementing prompt and efficient management and secondary prevention strategies. Despite significant improvements in management, the in-hospital mortality and morbidity associated with AKI remain high. A significant number of patients who survive the AKI have chronic sequelae with worsening of their underlying kidney disease and in some cases progression to ESRD requiring dialysis. Delay in the early detection of AKI due to insensitivity of serum creatinine as an early biomarker has been one of the important obstacles in evaluating and applying potentially effective early interventions.

DEFINITION AND CLASSIFICATION

Definition

There are many different published definitions of AKI based on changes of serum creatinine and urine output. Two recent and highly publicized consensus definitions and classification systems have been proposed. The Acute Dialysis Quality Initiative's RIFLE criteria stratified AKI into five groups: renal risk, renal injury, renal failure, renal loss, and ESRD (Fig. 68.1).³ This classification has been proposed to allow consistency across studies for greater ability to compare clinical results.

With current data that even small changes in serum creatinine are associated with increased mortality,⁴ the Acute Kidney Injury

Network (AKIN) derived a consensus definition^{5,6} that defines stage 1 of AKI as an absolute increase in creatinine concentration of 0.3 mg/dl (26 μ mol/l) or greater or a 50% to 100% increase from baseline (see Fig. 68.1). Studies comparing the sensitivity of AKI detection between these two classification systems, however, showed contradictory results in different in-hospital populations.⁷ Most attention has been focused on the first three categories of RIFLE (RIF) in comparisons with the three stages of AKIN. There remains some variation in how the criteria are interpreted and used in the literature, particularly with respect to the use of urine output criteria, the choice of baseline creatinine, and the use of the change in the estimated glomerular filtration rate (GFR) rather than the change in creatinine.

A recent analysis from the Program to Improve Care in Acute Renal Disease (PICARD) study group revealed that there is a changing spectrum of AKI in the critically ill, characterized by a large burden of comorbid disease and extensive extrarenal complications, resulting in the need for dialysis in the majority of patients. There is also wide variation across institutions in patient characteristics and practice patterns.⁸ The general in-hospital incidence of AKI is at least 0.5% but may be as high as 13%, depending on the definitions used. In specialized settings (e.g., in intensive care units), the reported incidence of AKI varies from 25% to more than 45%; a study of 120,000 patients reported an incidence of AKI within 24 hours of admission to the intensive care unit of 36% with use of the RIFLE criteria.⁹ We have recently reported that the time dependency of percentage changes in serum creatinine concentration after severe AKI are highly dependent on baseline kidney function, a feature that is not incorporated into the RIFLE criteria (Fig. 68.2).¹⁰

Classification

For the purpose of diagnosis and management, AKI can be broadly divided into prerenal, intrarenal, and postrenal (see Chapter 66 and Fig. 66.1). Most intrarenal AKI is related to tubular injury often associated with interstitial changes. Acute tubular injury is most often caused by ischemia or nephrotoxic injury to the kidney.

Although the term *acute tubular necrosis* has been generally applied to cases in which the AKI is due to tubular injury, it is a misnomer in many cases, especially when the insult is mild because necrosis may not dominate the pathologic picture. Rather, the cell death may be primarily apoptotic, and vasoconstriction may predominate in some cases; the cells may be injured but not so severely as to result in death. It is not appropriate to use the terms *acute kidney injury*, *acute renal failure*, and *acute tubular necrosis* interchangeably, as is often done.

Figure 68.1 RIFLE and AKIN criteria for diagnosis of AKI. RIFLE, risk, injury, failure, loss, ESRD; AKIN, Acute Kidney Injury Network; AKI, acute kidney injury; GFR, glomerular filtration rate; S_{Cr} , serum creatinine; UO, urinary output.

RIFLE and AKIN Criteria for Diagnosis of AKI		
RIFLE Classification ⁽³⁾		
	GFR Criteria	Urine Output Criteria
Risk	S _{Cr} >1.5 x baseline or ΔGFR >25% reduction	UO <0.5 ml/kg/h x 6 h
Injury	S _{Cr} >2.0 x baseline or ΔGFR >50% reduction	UO <0.5 ml/kg/h x 12 h
Failure	S _{Cr} >3.0 x baseline or ΔGFR >75% reduction or S _{Cr} >4.0 mg/dl	UO <0.3 ml/kg/h x 24 h or anuria x 12 h
Loss	Persistent acute renal failure = Complete loss of function for >4 wk	
ESRD	End-stage renal disease > 3 months	
AKIN Classification ⁽⁶⁾		
Stage	Serum Creatinine Criteria	Urine Output Criteria
1	ΔS _{Cr} ≥ 0.3 mg/dl (30μmol/l) or S _{Cr} ≥ 1.5, ≤ 2.0 x baseline	UO < 0.5 ml/kg/h x 6 h
2	S _{Cr} > 2.0, ≤ 3.0 x baseline	UO < 0.5 ml/kg/h x 12 h
3	S _{Cr} > 3.0 x baseline or S _{Cr} ≥ 4.0 mg/dl with an acute rise ≥ 0.5 mg/dl (50μmol/l) or on renal replacement therapy	UO < 0.3 ml/kg/h x 24 h or anuria x 12 h

Figure 68.2 A model of time-dependent changes in S_{Cr} concentrations after an abrupt 90% reduction in $CrCl$, reflecting the pattern of increase at four different stages of baseline kidney function (no CKD and stages 2 to 4 CKD). Solid squares show the point at which a 100% increase in S_{Cr} has occurred; open triangles show the point at which an increase of 1.0 mg/dl in S_{Cr} has occurred. S_{Cr} , serum creatinine; $CrCl$, creatinine clearance; CKD, chronic kidney disease. (Reprinted with permission from reference 10.)

DIAGNOSIS AND CLINICAL EVALUATION OF ACUTE KIDNEY INJURY

Early Detection of Acute Kidney Injury

The delay in early diagnosis of AKI has been a major impediment to development of newer preventive strategies for AKI. The approaches to the early detection of AKI include identification and monitoring of at-risk populations and development of more sensitive biomarkers. Several risk stratification scoring systems for AKI after cardiac surgery, vascular surgery, general surgery, contrast-induced nephropathy, and trauma have been explored. These have included the Acute Physiology and Chronic Health Evaluation (APACHE) I or II score, which is not focused on the kidney but rather is a general severity of illness scoring system. The Cleveland Clinic Foundation (CCF) score is a preoperative AKI risk score consisting of 11 preoperative variables including gender, congestive heart failure, left ventricular ejection fraction, use of intra-aortic balloon counterpulsation, chronic lung disease, insulin-requiring diabetes mellitus, previous cardiac surgery, emergency surgery, valve surgery, procedures other than coronary bypass or valve, and serum creatinine. As an example of the use of the CCF scoring system, the factors found to be related to a higher incidence of AKI after cardiac surgery in a study of 34,562 surgeries were male gender, postoperative intra-aortic balloon pump, congestive heart failure, ejection fraction below 35%, coronary artery bypass grafting plus valve surgery, diabetes mellitus, chronic obstructive pulmonary disease, and peripheral vascular or cerebrovascular disease.¹¹ For contrast nephropathy, risk factors are age, CKD, diabetes mellitus, volume depletion, nephrotoxic drugs, hemodynamic instability, nonsteroidal anti-inflammatory agents, and other superimposed kidney injury such as atheroemboli or as occurs in sepsis.

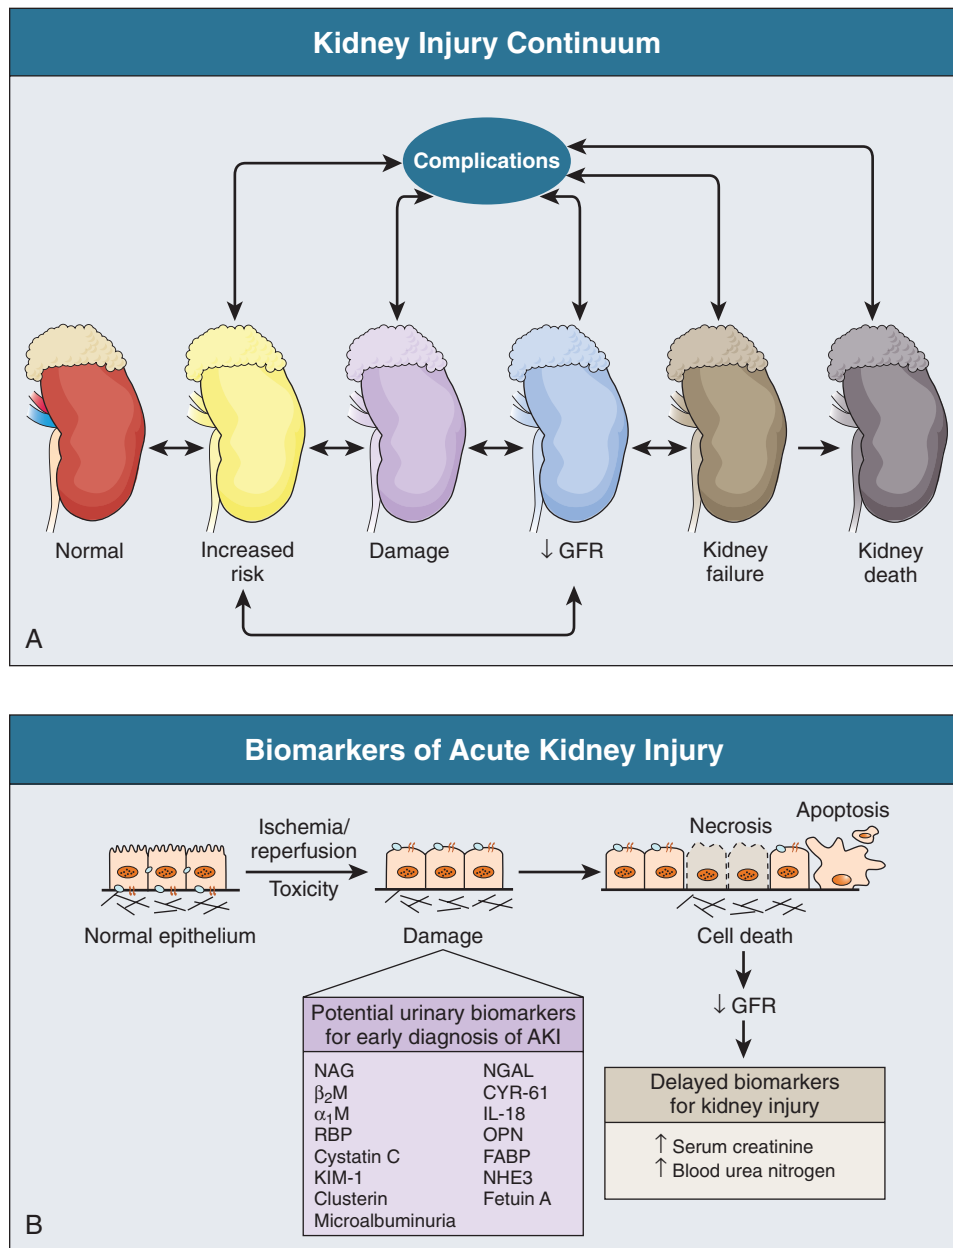

Figure 68.3 A, Kidney injury continuum. There are various reversible stages of AKI, depending on the severity of insult, ranging from increased risk to damage followed by decrease in GFR further progressing to kidney failure and death. **B,** Biomarkers of acute kidney injury. The traditional markers used to diagnose AKI, blood urea nitrogen and creatinine, are insensitive, are nonspecific, and do not adequately differentiate between the different stages of AKI. A group of urinary biomarkers of AKI are being evaluated, some of which will facilitate earlier diagnosis and specific preventive and therapeutic strategies, ultimately resulting in fewer complications and improved outcomes. GFR, glomerular filtration rate; NAG, *N*-acetylglucosaminidase; β_2 M, β_2 -microglobulin; α_1 M, α_1 -microglobulin; RBP, retinol-binding protein; KIM-1, kidney injury molecule 1; NGAL, neutrophil gelatinase-associated lipocalin; CYR-61, cysteine-rich protein 61; IL-18, interleukin-18; OPN, osteopontin; FABP, fatty acid-binding protein; NHE3, sodium-hydrogen exchanger isoform 3. (Reprinted with permission from references 12 and 13.)

There is a great deal of interest in the potential utility of various blood and urinary biomarkers, which can contribute either alone or in combination with the clinical markers described before to the diagnosis and prognosis of AKI. Figure 68.3 depicts the continuum of kidney injury severity and a number of biomarkers that have been proposed to be useful in early detection. Not all of these biomarkers are created equal, however, and a few are more likely than others to be useful because of stability of analytes, sensitivity and specificity, rapid assay availability, and cost-effectiveness. For a more complete overview of the potential urinary biomarkers, the reader is referred to recent reviews.^{12,13}

Serum creatinine has limitations as a marker for the early detection of AKI. The serum creatinine concentration depends not only on urinary clearance of creatinine but also on the rate of production and the volume of distribution. Furthermore, serum creatinine concentration does not accurately reflect GFR

in the non-steady-state condition of AKI. Substantial rises in serum creatinine are often not witnessed until 48 to 72 hours after the initial insult to the kidney. In addition, significant renal disease can exist with minimal or no change in creatinine; because a considerable “renal reserve” exists in the individual with normal renal function, the serum level of creatinine can be influenced by numerous nonrenal factors (see Chapter 3). Correct interpretation of serum creatinine concentrations across centers is also hampered by the variation in calibration of different creatinine assays.

Cystatin C has been receiving a great deal of attention as a better marker of kidney function compared with serum creatinine. Although it has not yet been well validated as a GFR indicator in AKI, studies have found cystatin C to be an early and reliable marker of AKI in patients in intensive care units.

β_2 -Microglobulin and α_1 -microglobulin have been reported as useful markers for proximal tubular damage. Limitations are

associated with less specificity because diseases other than kidney injury can also affect their serum levels and thus affect the urinary concentrations.

N-Acetylglucosaminidase is increased in the urine in many AKI settings. Its value in AKI detection is limited because the enzyme activity is sensitive to urine pH and some certain nephrotoxins.

Kidney injury molecule 1 (KIM-1) is a glycoprotein that is highly upregulated in proximal tubular cells injured by ischemia or nephrotoxins in animals and humans and is not produced to any significant extent, at levels that will affect urinary values, by any other organ. The ectodomain of this membrane-associated mucin-rich molecule is shed into the urine of human and rodent kidneys with renal injury, but it is not found in urine produced by healthy kidneys. Recent evaluation in human disease indicates that it is much more highly upregulated in AKI compared with acute renal dysfunction not related to ischemia or toxins and chronic renal failure. Recently, the two regulatory agencies, the U.S. Food and Drug Administration and the European Medicines Agency, have included KIM-1 in the small list of urinary kidney tubular injury biomarkers (together with β_2 -microglobulin, albumin, and total protein) that they will now consider in the evaluation of kidney tubular damage, as part of their respective drug review processes during animal studies of new drugs, and these regulatory agencies have encouraged its further use in clinical studies to amass more data on kidney biomarkers.^{14,15} Importantly, KIM-1 is not elevated in prerenal disease.

Neutrophil gelatinase-associated lipocalin (NGAL) is markedly upregulated and abundantly expressed in the kidney after renal ischemia. Urinary NGAL has been shown to be a sensitive marker for the early detection of AKI in a large number of studies.¹⁶ NGAL, also known as lipocalin 2 or siderocalin, was first discovered as a 25-kd protein in granules of human neutrophils. NGAL is normally expressed at low levels in a number of organs including kidney, breast, liver, small intestine, prostate, stomach, lymphoid cells, thymus, and lungs. It is upregulated in the distal tubule after injury to the kidney and has been found to be promising as an early diagnostic and predictive urinary marker of injury in many clinical states. Much of the early work on this molecule was done in children, but many studies more recently have been conducted in adults.

Urinary interleukin-18, fatty acid-binding protein (FABP1), and albuminuria also have shown important potential utility in the early diagnosis of AKI.

Given the urgent need for more timely diagnosis of AKI and the limitations of serum creatinine in the early detection of renal dysfunction, we believe that one or more of the new serum (cystatin C) and urine (such as KIM-1, *N*-acetylglucosaminidase, and NGAL) biomarkers will soon be monitored in high-risk patients. Additional regulatory approval, however, and more clinical studies in varying populations of patients will be necessary before physicians can be confident in the sensitivities and specificities of these markers either alone or in combination. In the future, we are likely to have point-of-care bedside technology including dipsticks to provide online noninvasive detection of the onset and severity of kidney injury.

DIFFERENTIAL DIAGNOSIS OF ACUTE KIDNEY INJURY

The differential diagnosis of AKI should aim to answer the following five questions:

1. Is the renal failure acute, acute on chronic, or chronic?
2. Is there evidence of true hypovolemia or reduced effective arterial blood volume, that is, prerenal AKI?
3. Has there been a major vascular occlusion?
4. Is there evidence of parenchymal renal disease other than acute tubular necrosis?
5. Is there renal tract obstruction, that is, postrenal AKI?

Community-acquired AKI can usually be attributed to a single cause, whereas AKI acquired on a hospital ward mostly occurs in the setting of comorbidity and is often multifactorial. AKI acquired in the intensive care unit is almost always multifactorial.

The differential diagnosis of AKI is typically made in conjunction with the clinical history, physical examination findings, and blood and urine laboratory values. Ultrasound of the urinary tract is useful to exclude postrenal AKI. Renal biopsy is reserved for patients in whom prerenal and postrenal AKI have been excluded and the cause of intrarenal AKI is unclear. An algorithm summarizing the approach to a patient with presumed AKI is provided in Figure 68.4. This approach will reveal the likely cause of AKI in most patients.

Acute Kidney Injury Versus Chronic Kidney Disease

It is extremely important to discriminate AKI from chronic renal failure because AKI can potentially resolve if the causal event can be removed and the patient is appropriately supported. The patient's history and information about prior serum creatinine values are invaluable for differentiation of AKI and chronic renal failure if they are available. Radiographic evidence of renal osteodystrophy or small scarred kidneys is also conclusive to establish the chronic impairment of kidney function. However, in some cases of chronic renal disease (e.g., diabetic nephropathy, amyloidosis, polycystic kidney disease), renal size can be normal or increased. The findings of anemia, hyperphosphatemia, hypocalcemia, hyperparathyroidism, neuropathy, and band keratopathy on presentation would suggest chronic renal failure (albeit not completely definitive). Patients with CKD are at high risk for development of episodes of AKI. In such cases, the kidney size is somewhat less useful as a diagnostic tool. An abrupt and unexpected rise in the baseline creatinine value in such patients should prompt an evaluation for superimposed, potentially reversible AKI.

Clinical Assessment

The assessment of patients with AKI requires a careful history and record review, a thorough physical examination, and the judicious interpretation of laboratory data. Careful recording of remote and recent serum creatinine levels over time, incorporating drug therapy and interventions, is invaluable for differential diagnosis and for the identification of the possible cause of AKI. Information obtainable by history should include type and duration of symptoms for urinary difficulty, estimates of volume of urine, history of urinary tract infection or stone disease, recent surgery and drugs used. Clinical, pharmacy, nursing, and radiology records should be reviewed for evidence of recent administration of nephrotoxic medications (e.g., nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors, or angiotensin receptor blockers) or radiocontrast agents.

Physical examination will reveal signs important for the diagnosis of the etiology of AKI. Some of these include signs of sepsis or malignant disease, volume status, skin or pulmonary manifestations of systemic disease, cardiac rhythm abnormalities or

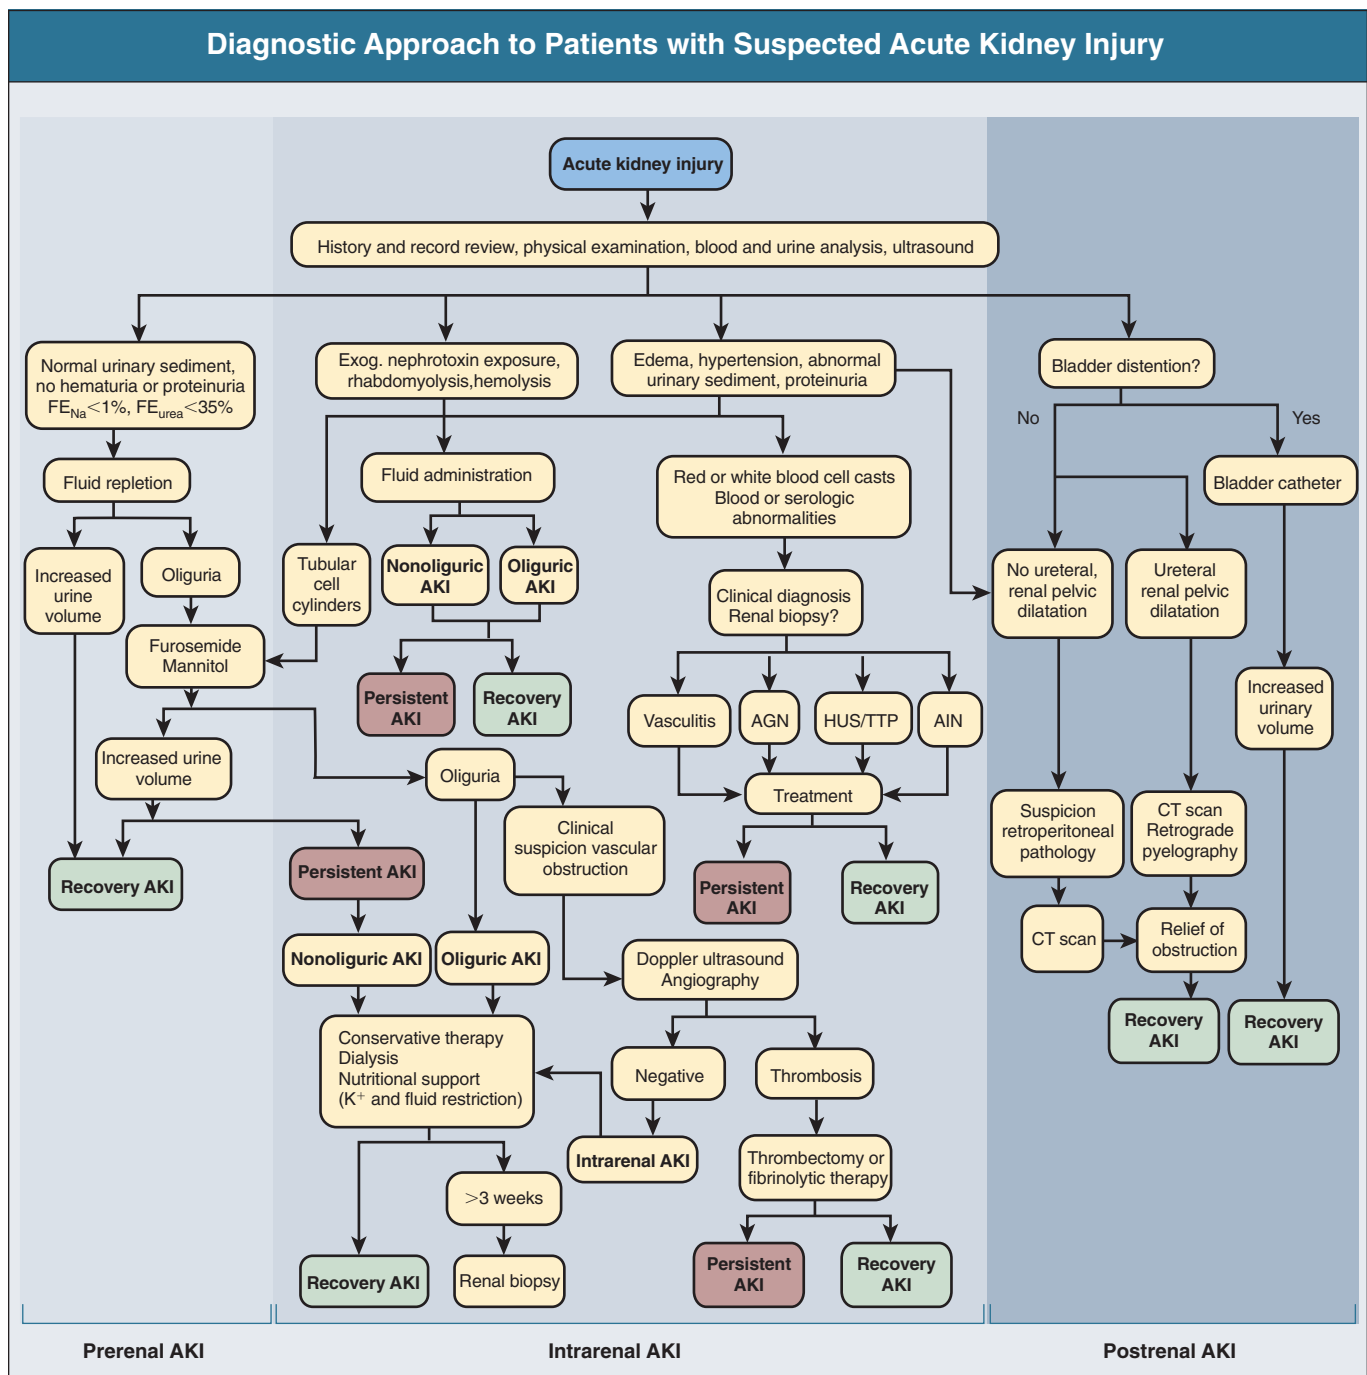

Figure 68.4 Diagnostic approach to patients with suspected AKI. AGN, acute glomerulonephritis; AIN, acute interstitial nephritis; CT, computed tomography; Exog., exogenous; HUS/TTP, hemolytic-uremic syndrome/thrombotic thrombocytopenic purpura.

congestive heart failure, manifestations of abnormal liver function, edema or ascites, and a hydronephrotic mass presenting as a mass in the flank or a distended bladder presenting as a suprapubic mass. A complete pelvic examination in women and a rectal examination for all patients are mandatory. Prerenal causes should be suspected especially in AKI patients with clinical symptoms of thirst or orthostatic hypotension or tachycardia, reduced jugular venous pressure, decreased skin turgor, and reduced axillary sweating. In critically ill patients, invasive hemodynamic monitoring (central venous or Swan-Ganz catheterization) is often necessary. Although most AKI is either prerenal or due to ischemia or nephrotoxins, patients should be assessed

carefully for the evidence of other renal parenchymal diseases; many of these are treatable, and their diagnosis alters management and prognosis.

In any patients with AKI, an obstructive cause must be excluded because prompt intervention to relieve obstruction can result in improvement or complete recovery of renal function. If it is unnoticed, significant delays in the diagnosis can lead to adverse long-term sequelae.

Serum Creatinine Concentration

Although serum creatinine demonstrates poor sensitivity and specificity in early detection of AKI, in current clinical practice,

renal function is still commonly monitored in patients with AKI by following the daily variations in serum creatinine concentration. The serum creatinine concentration tends to rise progressively and usually at a rate greater than 0.3 to 0.5 mg/dl (26 to 44 μ mol/l) per day in AKI. A slow rate of rise with periodic downward fluctuations associated with volume administration or improvement in cardiac function favors prerenal factors as causes of the AKI.

Serum BUN/Creatinine Ratio

The plasma BUN/creatinine ratio is usually 10 to 15:1 (when both are expressed as mg/dl; 40 to 60 when expressed as mmol/l) in normal individuals and in AKI but may be greater than 20:1 in prerenal AKI because of the increase in the passive reabsorption of urea. Thus, a high ratio is frequently touted as suggestive of prerenal AKI, but this is unreliable because the BUN will also rise when urea production is increased from gastrointestinal bleeding, tissue breakdown, high catabolic status (e.g., sepsis), or impairment of protein anabolism (administration of corticosteroids or tetracycline). The plasma BUN/creatinine ratio can also exceed 20:1 when a loss of muscle mass in a chronically ill or elderly patient lowers creatinine production and hence the plasma creatinine concentration without a change in GFR. In addition, prerenal AKI should not be excluded by a normal ratio because diminished urea production (due to decreased protein intake or underlying liver disease) can prevent the expected rise in the BUN by increased tubular reabsorption.

Urinalysis

Assessment of the urine is a mandatory and inexpensive tool in the evaluation of AKI. Urine volume is of varying utility in the differential diagnosis, although a patient whose urine output has been less than 30 ml/h for 6 hours will often have AKI. Analysis of the sediment and supernatant of a centrifuged urine specimen is valuable for differential diagnosis of AKI. The urinalysis should involve a dipstick analysis for pH, glucose, red blood cells, white blood cells, and protein.

Urine Sediment Urine microscopy is one of the oldest and most commonly used tests for differential diagnosis of AKI. Microscopic examination should be performed on freshly centrifuged urine sediments, evaluating the presence of cells, casts, and crystals (Figs. 68.5 and 68.6). The urinalysis is normal or nearly normal in pure prerenal AKI; hyaline casts may be seen, but these are not an abnormal finding. In comparison, the classic urinalysis in ischemic or toxin-induced AKI reveals “muddy brown” granular and epithelial cell casts and free epithelial cells. It was reported recently that a simple urinary cast scoring system, based on grading the level of casts and epithelial cells, had potential value in diagnosis of tubular injury and might also be useful for predicting renal outcomes.¹⁷ More data will be necessary to confirm the utility of this particular system. Casts may be absent, however, in approximately 20% to 30% of patients with ischemic or nephrotoxic AKI, and thus they are not a requisite for diagnosis. Patients with postrenal AKI may also present with benign sediment, although hematuria and pyuria are common in patients with intraluminal obstruction or prostatic disease.

Urine Osmolality Measurement of the urine osmolality can also be helpful in differential diagnosis. Loss of concentrating ability is an early and almost universal finding in AKI; the urine osmolality is below 450 mosmol/kg in almost all cases and often below 350 mosmol/kg. In contrast, a urine osmolality above

500 mosmol/kg is highly suggestive of prerenal AKI because it usually reflects both a hypovolemic stimulus to the secretion of antidiuretic hormone and the maintenance of normal tubular function. This test becomes less discriminatory if the patient is receiving diuretics, which can interfere with concentrating ability. If the urinary osmolality remains high with diuretics, the test is useful in pointing to prerenal azotemia. The interpretation of lower urinary osmolalities, however, is more ambiguous because this may reflect the effect of the diuretic rather than the underlying capacity of the kidney to concentrate.

Urinary Protein Increased urinary protein excretion, characteristically less than 1 g/day, is a common finding in ischemic or nephrotoxic AKI and reflects both failure of injured proximal tubule cells to reabsorb normally filtered protein and excretion of cell debris (tubule proteinuria). Proteinuria greater than 1 g/day suggests injury to the glomerular ultrafiltration barrier (glomerular proteinuria) or excretion of paraproteins such as myeloma light chains.

Urinary Sodium Concentration The urine sodium concentration tends to be low in prerenal AKI (<20 mmol/l) as the kidney appropriately attempts to conserve sodium and high in intrarenal AKI (>40 mmol/l) due in part to the adverse effects of the tubular injury on sodium reabsorption. There is, however, frequent overlap, often due to large variations in water reabsorption, which can also affect the urine sodium concentration. As an example, a prerenal patient who has increased secretion of antidiuretic hormone and an intact concentrating process may have a higher than expected urine sodium concentration despite excreting relatively little sodium. Conversely, decreased water reabsorption can lower the urine sodium by dilution. Thus, the fractional excretion of sodium (FE_{Na})* is a better test because it evaluates only sodium handling (the fraction of the filtered sodium that is excreted) and is not affected by changes in water reabsorption.

Fractional Excretion of Sodium If tubular function is intact, renal vasoconstriction is associated with enhanced tubular sodium reabsorption. Specifically, the fraction of filtered sodium that is rapidly reabsorbed by normal tubules of the vasoconstricted kidney is significantly greater than 99%. Thus, when there is a fall in GFR secondary to renal vasoconstriction with intact tubular function, the FE_{Na} is less than 1%. An exception to this physiologic response of the normal kidney to vasoconstriction occurs when the patient is receiving a diuretic, including mannitol, or has glucosuria, which decreases tubular sodium reabsorption and increases FE_{Na} . FE_{Na} is useful in many clinical scenarios but loses diagnostic value in patients receiving diuretics or with CKD because of intrinsic impairment of efficient sodium reabsorption associated with chronic tubulointerstitial disease and chronic adaptation of sodium excretion, leading to enhanced sodium excretion. The diagnostic specificity of FE_{Na} in distinguishing prerenal azotemia from intrarenal causes of AKI may also be affected by the fact that the patient may actually be progressing from a prerenal azotemic state to established AKI. The FE_{Na} has also been found to be less than 1% in some patients with a variety of conditions other than prerenal AKI (e.g., contrast media-induced or pigment-induced AKI, acute glomerulonephritis and vasculitis, and some cases of acute interstitial

* $FE_{Na} = (\text{urine sodium} \times \text{plasma creatinine}) / (\text{plasma sodium} \times \text{urine creatinine}) = (\text{urine sodium} / \text{plasma sodium}) / (\text{urine creatinine} / \text{plasma creatinine})$.

Figure 68.5 Examples of urinary sediments in common cases of AKI.

A, Epithelial cell aggregate. **B**, Hyaline cast as can be seen in prerenal acute kidney injury. **C**, Epithelial cast as can be seen in early acute tubular necrosis (arrows indicate epithelial cells). **D**, Muddy brown cast, typical of established acute tubular necrosis. **E**, Erythrocyte cast as seen in glomerulonephritis and vasculitis. *Inset*: Hemoglobin cast. **F, G**, Two forms of indinavir crystals.

nephritis and obstruction). In patients who were not taking diuretics, FE_{Na} was reportedly able to distinguish transient from persistent AKI (determined by whether serum creatinine returned to baseline within 7 days). Despite these many caveats, FE_{Na} can be very useful when it is considered in the context of other clinical signs and laboratory studies. A fractional excretion of urea of less than 35% favors renal vasoconstriction rather than intrarenal AKI as a cause of the impaired kidney function in the presence of diuretics.¹⁸

Urine to Serum Creatinine Concentration The urine to plasma creatinine concentration (U_{Cr}/P_{Cr}) is a way to estimate tubular water reabsorption. The creatinine concentration in the glomerular filtrate is equal to that in the plasma and then rises progressively as water but not creatinine is reabsorbed; creatinine

secretion will also make a modest contribution to the elevation in the ratio. Patients with prerenal AKI generally have a urine to plasma creatinine ratio above 40, indicating that more than 39/40 or 97.5% of the filtered water has been reabsorbed. Water reabsorption is less efficient in AKI, and the U_{Cr}/P_{Cr} is usually below 20. The most important clinical and laboratory variables in the differential diagnosis between prerenal and renal AKI are listed in Figure 68.7.

Imaging Studies

Imaging of the urinary tract by ultrasound (see Chapter 5) is useful to exclude postrenal AKI. Small kidneys are a clue to the diagnosis of chronic kidney diseases. A plain film of the abdomen, with tomography if necessary, is a valuable initial screening

Clinical and Laboratory Variables in the Differential Diagnosis Between Prerenal and Renal AKI		
	Prerenal	Renal
History	GI, urinary, skin volume loss, blood loss or third spacing	Drugs or toxin exposure, hemodynamic change
Clinical presentation	Hypotension or volume depletion	No specific symptoms or signs
Laboratory studies		
BUN/ S_{Cr}	>20	<20
Sediment	Normal to few casts	"Muddy brown" casts
U_{osm} (mmol/kg)	>500	<350
Proteinuria	None to trace	Mild to moderate
U_{Na} (mmol/l)	<20	>40
FE_{Na} (%)	<1	>1
FE_{Urea} (%)	<35	>35
U_{Cr}/S_{Cr}	<20	>40
Novel biomarkers	None	KIM-1, cystatin C, NGAL, CYR61, others

technique in patients with suspected nephrolithiasis. Computed tomography and magnetic resonance imaging are also useful in detecting obstruction. Pelvicalyceal dilation is usual in patients with urinary tract obstruction (98% sensitivity); however, dilation may be absent immediately after obstruction or in patients with ureteral encasement (e.g., retroperitoneal fibrosis, neoplasia). Retrograde pyelography and anterograde pyelography are more definitive investigations in cases in which obstruction is highly suspected but imaging studies have not adequately defined the cause. These studies can provide precise localization of the site of obstruction. Doppler ultrasound and magnetic resonance angiography have proved useful for assessment of patency of renal arteries and veins in patients with suspected vascular compromise or obstruction as a prerenal cause of AKI; however,

contrast angiography is usually required for definitive diagnosis, and the specific link of gadolinium as a causative agent in nephrogenic systemic fibrosis (see Chapter 84) makes it prudent to avoid this contrast agent.

Renal Biopsy

Renal biopsy is reserved for patients in whom prerenal and postrenal AKI have been excluded and the cause of intrinsic renal AKI remains unclear. Renal biopsy is particularly useful when clinical assessment and laboratory investigations suggest diagnoses other than ischemic or nephrotoxic injury that may respond to disease-specific therapy. Examples include rapidly progressive glomerulonephritis, vasculitis, systemic lupus erythematosus,

and acute interstitial nephritis. Renal biopsy is also very useful when there is AKI in renal allograft recipients and the therapy will depend critically on whether this is due to immunologic rejection or another cause.

PATHOLOGY OF ACUTE KIDNEY INJURY

Tubular injury in ischemic AKI is usually most severe within the outer medulla of the kidney, involving both the pars recta (S₃ segments) of the proximal tubule and the medullary thick ascending limb of the distal nephron.¹⁹ The typical histologic features of human proximal tubular injury include vacuolation, loss of brush border, and presence of intratubule casts (Fig. 66.3). Necrosis of tubular cells is patchy and is not usually dominant in the biopsy specimen, perhaps in part because most biopsy specimens are from the cortex and the outer medulla is not sampled adequately. Apoptosis of tubular cells is present in renal biopsy specimens from humans with AKI, and evidence of cellular regeneration is often seen, most commonly in those areas of greatest tubular cell loss. Furthermore, regenerative changes and signs of fresh epithelial injury are often observed in the same biopsy specimen, suggesting that recurrent episodes of tubular ischemia continue to occur during the maintenance phase of AKI. The morphologic appearance of the common forms of toxic AKI is similar to that of ischemic AKI. Correlations of morphologic findings to functional endpoints has been difficult, especially because the biopsy represents a limited view of the pathologic process at one point in time and usually samples only the cortex of the kidney.

Prevention and Nondialytic Management of Acute Kidney Injury

Etienne Macedo, Josée Bouchard, Ravindra L. Mehta

Acute kidney injury (AKI) acquired in the hospital is often due to a combination of insults. The most common associated causes are failure of renal autoregulation, direct nephrotoxicity, ischemia-reperfusion, and inflammatory states. AKI severity predicts adverse outcomes, such as requirement for renal replacement therapy (RRT), length of hospital stay, and mortality. In addition, the widespread use of the RIFLE and AKI classification systems (see Chapter 68) has shown that even small changes in glomerular filtration rate (GFR) are associated with increased mortality.¹ Furthermore, AKI contributes to dysfunction of other organs, such as heart, lung, brain, and liver. Consequently, primary prevention and early diagnosis of AKI are of central clinical importance. Once a decline in GFR is detected, secondary prevention to attenuate the effects of injury and treatment of the consequences of injury are necessary.

RISK ASSESSMENT

Considering the conceptual model of AKI illustrated in [Figure 69.1](#), the first step in preventing AKI is an adequate risk assessment. The initial care of patients at risk should be focused on identification and, if possible, reversal of the risk factors. [Figures 69.2 and 69.3](#) summarize risk factors in different clinical settings. For a further discussion of risk factors and scoring systems, see [Chapters 67 and 68](#).

PRIMARY PREVENTIVE MEASURES

Optimizing Volume Status and Hemodynamic Status

Regardless of the nature of an insult, hemodynamic stabilization with optimization of the cardiac output and blood pressure (BP) is a key factor in prevention of AKI. The general aim is to optimize volume status based on physiologic measurements, to maintain adequate hemodynamic status and cardiac output to ensure renal perfusion, and to avoid further insults (e.g., hypotension, hypovolemia). Therefore, fluid management is an important intervention for patients in the initiation or extension phase of AKI. Volume expansion can decrease the risk of AKI in the perioperative setting of major vascular surgeries, after renal transplantation and procedures to correct obstructive jaundice. In these clinical scenarios, fluid volume administration is most beneficial at the initiation phase. However, once the injury is initiated and the extension phase starts, the impact of volume expansion with intravenous fluids on clinical outcomes has not been well described and needs to be balanced with the unwanted consequence of fluid accumulation and overload.

Assessment of the volume status is challenging, particularly in patients in the intensive care unit.² In most cases, the effect of fluid expansion on the general hemodynamic status and renal function is retrospective and frequently evaluated by trial and error. In patients in the prerenal phase of AKI, fluid expansion will increase organ perfusion, and renal function can improve. In other circumstances, as in patients with severe congestive heart failure (CHF) or diastolic dysfunction, renal perfusion is inadequate despite normal volume status or volume overload. In these patients, fluid expansion can lead to worsening of cardiac function and pulmonary edema.

There are no specific guidelines for optimizing hemodynamic and fluid status for renal function preservation, but extrapolation of data from clinical settings associated with AKI can be instructive. To improve the evaluation of volume status, international guidelines for management of sepsis from the Surviving Sepsis Campaign recommend invasive monitoring with measurements of central venous pressure and venous oxygen saturation (superior vena cava or mixed) based on the early goal-directed therapy approach.³ The Rivers study randomized patients with severe sepsis or septic shock to receive 6 hours of standard therapy or 6 hours of early goal-directed therapy before admission to the intensive care unit. The protocol ensured that all patients had a central venous pressure of between 8 and 12 mm Hg, a mean arterial pressure (MAP) above 65 mm Hg, and a urine output of more than 0.5 ml/kg per minute by the administration of 500-ml boluses of crystalloid or colloid and vasopressor agents as necessary. Early goal-directed therapy patients received a central venous catheter capable of measuring ScvO₂, and they also had to achieve ScvO₂ above 70%, pursued by red blood cell transfusion for anemic patients (hematocrit, <30%) and dobutamine therapy for patients above that threshold. This initial approach, applied for 6 hours, reduced the mortality rate, need of mechanical ventilation and therapy with vasopressors, and length of hospital stay.

A number of studies have since established the benefits of adequate fluid expansion and earlier vasopressor administration for rapid shock reversal,⁴ and the concept of goal-directed therapy is an attempt to define resuscitation endpoints in early septic shock. However, fluid expansion should be stopped when patients are no longer fluid responsive; late and prolonged aggressive resuscitation in critically ill patients is associated with fluid overload and worse outcomes. Data from the Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network⁵ indicate that after initial resuscitation, a conservative approach to fluid administration is associated with faster weaning from mechanical ventilation and decreased length of intensive care unit stay without any deterioration of kidney function or worse

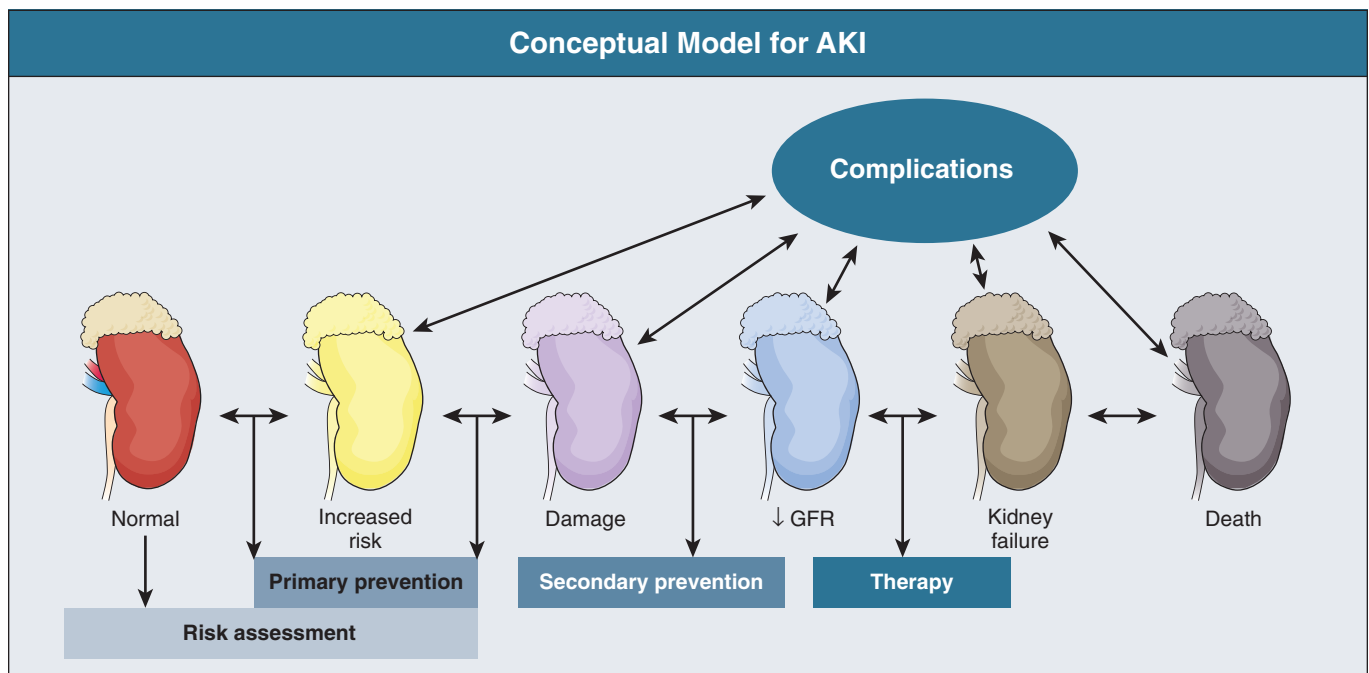

Figure 69.1 Conceptual model for acute kidney injury (AKI). GFR, glomerular filtration rate. (Modified with permission from reference 2.)

Major Risk Factors for Acute Kidney Injury		
Patient Factors	Medications and Agents	Procedures
Pre-existing renal dysfunction	Nonsteroidal anti-inflammatory drugs	Cardiopulmonary bypass procedures
Sepsis		Surgery involving aortic clamp
Old age (>75)	Cyclooxygenase-2 inhibitors	Increased intra-abdominal pressure
Diabetes	Cyclosporine or tacrolimus	Large arterial catheter placement with risk for atheroembolization
Hepatic failure	Angiotensin-converting enzyme inhibitors	Liver transplantation
Atherosclerosis	Angiotensin receptor blockers	Kidney transplantation
Chronic hypertension		
Perioperative cardiac dysfunction	Use of venous or arterial radiocontrast agents	
Hypercalcemia		
Renal artery stenosis		

Figure 69.2 Major risk factors for acute kidney injury (AKI).

kidney outcomes.⁵ In conclusion, a liberal fluid approach as part of early goal-directed therapy appears to be beneficial during the first 6 hours of shock, and a conservative approach should be followed after resolution of shock. Whether these same principles apply for patients with AKI in the absence of shock is unknown. The potential risks of fluid accumulations and overload in the setting of AKI need to be considered.⁶

There is controversy about the optimal fluid to use for resuscitation in critically ill patients. The recent Saline versus Albumin

Fluid Evaluation (SAFE) trial of 6997 patients found that fluid resuscitation with saline or albumin resulted in similar relative risks of death in critically ill patients.⁷ There were also no significant differences in the proportion of patients with new single-organ and multiple-organ failure, length of intensive care unit stay, length of hospital stay, days of mechanical ventilation, or days of RRT. However, a follow-up subgroup analysis showed that use of albumin may be deleterious in patients with traumatic brain injury.⁸

Specific Risk Factors for the Development of Acute Kidney Injury in Common Clinical Situations					
Postoperative	Cardiac Surgery	Critically Ill	Sepsis	Contrast Nephropathy	Nephrotoxic Antibiotics
Hemodynamic	Preoperative $Sc_r > 2.1$ mg/dl	Active cancer	Serum bilirubin > 1.5 mg/dl	Systolic BP < 80 mm Hg for > 1 h and need for inotropic support	Amphotericin
Multiorgan failure	Preoperative IABP	Low serum albumin	Age	IABP 24 h after procedure	Volume depletion
Aortic cross-clamping	Heart failure		$Sc_r > 1.3$ mg/dl	Use of IABP	Concurrent other nephropathy
Congestive heart failure	LV ejection fraction $< 35\%$	High A-a gradient*	Elevated CVP > 8 cm	Heart failure (NYHA class 3 or 4)	Aminoglycosides
Sepsis	Combination of CABG + valve surgery	High intra-abdominal pressure	Hemodynamic instability	History of pulmonary edema	Preexisting renal dysfunction
Infection	Emergency surgery			$Sc_r > 1.5$ mg/dl or eGFR < 60 ml/min per m^2	Duration of therapy > 7 days
Hypertension	Valve surgery only			Volume of contrast > 100 ml	Sepsis
Cardiac instability	Previous cardiac surgery			Age > 75 yr	Volume depletion
Major vascular surgery	Other cardiac surgery			DM	Divided-dose regimens
Gastrointestinal and endocrine	Insulin-requiring diabetes			Anemia, blood loss (Hct: $< 39\%$ for men; $< 36\%$ for women)	Liver disease
Liver cirrhosis	COPD			Intra-arterial injection	Old age
Biliary surgery	ACE inhibitor therapy				
Obstructive jaundice	Female gender				
DM

ACE, angiotensin-converting enzyme; BP, blood pressure; CABG, coronary arterial bypass graft; CVP, central venous pressure; IABP, intra-aortic balloon pump; COPD, chronic obstructive pulmonary disease; DM, diabetes mellitus; eGFR, estimated glomerular filtration rate; Hct, hematocrit; LV, left ventricular; NYHA, New York Heart Association. *A-a gradient, alveolar-arterial oxygen gradient calculated by the sea-level standard formula $(713 \times FIO_2) - (PCO_2/0.8) - PaO_2$, where FIO_2 is fractional inspired oxygen concentration, PaO_2 is arterial partial oxygen pressure, and PCO_2 is partial carbon dioxide pressure. (Modified with permission from reference 51.)

Hydroxyethyl starch (HES) preparations are the most used nonprotein intravascular volume expanders. In addition to their efficiency in fluid management, they have anti-inflammatory properties and reduced cost compared with albumin. However, they potentially alter coagulation and platelet function as a result of their physicochemical characteristics and the electrolyte com-

position of the solvent. AKI is also a major concern with their use, and it is thought to be associated with the urine hyperviscosity leading to tubular lumen obstruction. This so-called osmotic nephrosis is characterized by tubular nephrosis-like lesions. The solutions exhibit different nephrotoxicity potential, as the pharmacokinetics of HES depends on the degree of substitution at

carbons 2 and 6 in the glucose ring in combination with the molecular weight and molar substitution. They are identified by three numbers, indicating the concentration of the solution, the mean molecular weight, and, the most significant one, the molar substitution (e.g., 10% HES 200/0.5 or 6% HES 130/0.4). Current clinical data on the third-generation HES 130/0.4 have reported no adverse effects on renal function in patients who are considered to be at particular risk (mild to severe renal dysfunction, advanced age, and high-dose therapy). Therefore, older and newer generations of HES differ, and adverse effects reported with older generations of HES should not be extrapolated to newer compounds. In summary, in patients at risk for AKI, the newer generation iso-oncotic HES (130/0.4, 6%) should be preferred, the dose should be limited, and renal function should be closely monitored, preferably every 12 to 24 hours.

Prevention of Contrast Medium Nephropathy

Common among the various protocols is the need to establish and to maintain an adequate hydration status. To prevent contrast medium–induced nephropathy (CIN), low-risk patients should increase their oral fluid intake and high-risk patients should receive intravenous hydration (Fig. 69.4). Hydration with isotonic saline started the morning of the procedure or immedi-

ately before in cases of emergency interventions is superior to half-isotonic (0.45%) saline.⁹ A randomized controlled trial (RCT) compared isotonic saline with isotonic sodium bicarbonate (154 mmol/l NaHCO₃ in 5% dextrose at 3 ml/kg per hour for 6 hours starting 1 hour before the procedure followed by 1 ml/kg per hour for the 6 hours after the procedure). CIN was significantly lower in the bicarbonate group, 2% versus 14% in the saline solution group.¹⁰ The rationale for isotonic bicarbonate is based on animal studies showing that bicarbonate is capable of scavenging reactive oxygen species, and the increased pH in the proximal tubule and the renal medulla associated with bicarbonate administration could reduce generation of superoxide. In addition, isotonic saline contains high amounts of chloride, with a potential vasoconstrictor effect on renal vasculature. Considering that most hydration studies with isotonic bicarbonate use shorter infusion protocols (only 1 hour) than those with isotonic saline (usually 12 to 24 hours), hydration with bicarbonate is also an attractive alternative in the setting of emergency procedures.

Although the superiority of bicarbonate was confirmed by four additional randomized trials reported, four others did not show a difference and a large retrospective cohort study found that use of bicarbonate was associated with increased risk of CIN. Joannidis and colleagues¹¹ conducted a meta-analysis to address

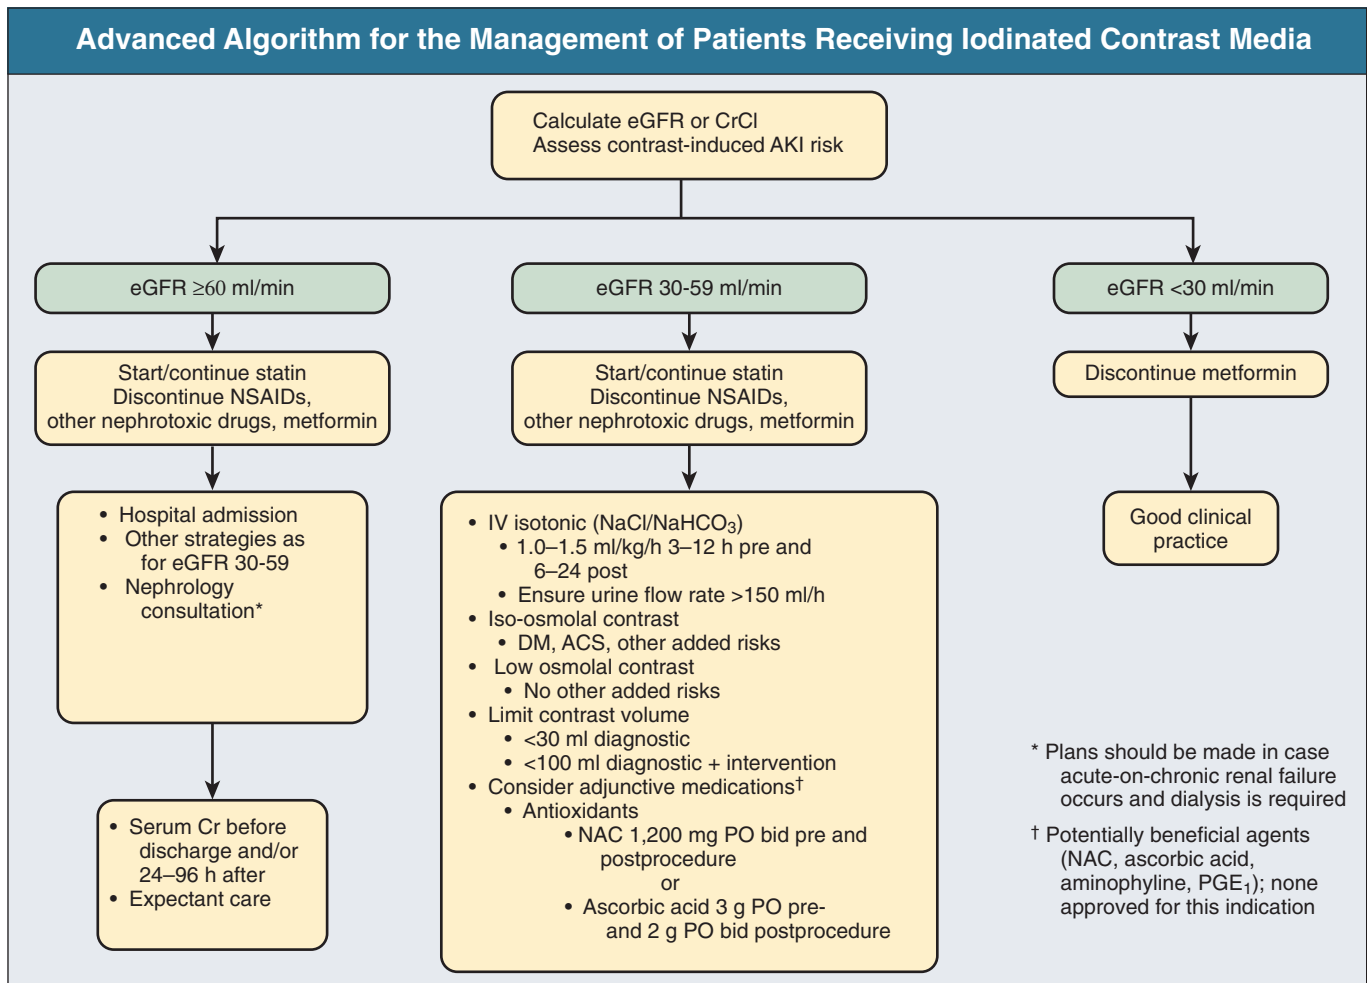

Figure 69.4 Advanced algorithm for the management of patients receiving iodinated contrast media. ACS, acute coronary syndromes; AKI, acute kidney injury; CrCl, creatinine clearance; DM, diabetes mellitus; eGFR, estimated glomerular filtration rate; NAC, *N*-acetylcysteine; NSAIDs, nonsteroidal anti-inflammatory drugs; PGE₁, prostaglandin E₁. (Modified with permission from reference 52.)

the discordant results of these trials. Although they confirmed that bicarbonate therapy is more effective in preventing CIN, the heterogeneity of the studies and publication bias were substantial, preventing clear and definitive conclusions.

Iodinated contrast medium can be categorized according to osmolality into high-osmolal contrast medium (~2000 mOsm/kg), low-osmolal contrast medium (600 to 800 mOsm/kg), and iso-osmolal contrast medium (290 mOsm/kg). The higher cost of the low-osmolality agents barred the complete replacement of high-osmolality iodinated contrast medium. The guidelines recommend the use of low-osmolality iodinated contrast medium for patients with increase risk of CIN. Evidence to date suggests that the iso-osmolal, nonionic contrast media are the least nephrotoxic, particularly after intraarterial administration, and should therefore be used in patients at high risk for CIN.

The volume of contrast material administered is also a crucial risk factor and an independent predictor of CIN. Based on the volume of contrast given (V) and the creatinine clearance (CrCl), a V/CrCl ratio above 3.7 was a significant and independent predictor of CIN in the general population. Administration of contrast material more than once in a short period is another risk factor, and contrast studies should be postponed at least 48 hours after the last infusion of contrast medium if possible.

The drugs used for CIN prevention are included in the section on pharmacologic approaches.

Prevention of Drug- and Nephrotoxin-Induced Acute Kidney Injury

Amphotericin

Amphotericin-associated nephrotoxicity can occur in as many as one third of treated patients, and the risk of AKI increases with higher cumulative doses. Lipid formulations seem to cause less nephrotoxicity compared with the standard formulation, amphotericin B deoxycholate. A recent review concluded that amphotericin B lipid complex, liposomal amphotericin B, and amphotericin B colloidal dispersion were significantly less nephrotoxic than amphotericin B deoxycholate. No studies have compared amphotericin B colloidal dispersion nephrotoxicity with other lipid formulations. The use of these formulations can help preserve renal function in patients with systemic fungal infections; however, they are significantly more expensive. Recently, alternative antifungal agents such as itraconazole, voriconazole, and caspofungin have been more commonly used in patients at high risk for AKI.

Angiotensin-Converting Enzyme Inhibitors, Angiotensin Receptor Blockers, and Nonsteroidal Anti-Inflammatory Drugs

Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) cause vasodilation of the efferent glomerular arteriole, further reducing intraglomerular pressure already compromised by the BP-lowering effect of these agents. In patients with renal dysfunction, they can contribute to a reduction in GFR. In patients with an increase in serum creatinine higher than 30% after the initiation of ACE inhibitor and ARB treatment, bilateral renal artery stenosis, stenosis of the renal artery in a solitary kidney, or diffuse intrarenal small-vessel disease should be suspected and these drugs should be discontinued.

Nonsteroidal anti-inflammatory drugs (NSAIDs) or cyclooxygenase 2 inhibitors should be used with caution in patients with atherosclerotic cardiovascular diseases (CVD), chronic

kidney disease (CKD), and intravascular volume depletion. As NSAIDs cause acute inhibition of cyclooxygenase (type 1 or 2), they can reduce GFR and renal blood flow. In critically ill patients, renal hypoperfusion due to decreased effective circulating volume is relatively common, and inhibition of prostaglandin-induced vasodilation may further compromise renal blood flow and exacerbate ischemic injury.

Aminoglycosides

Clinical evidence of AKI due to aminoglycoside nephrotoxicity usually occurs 5 to 10 days after initiation of the treatment; it is typically nonoliguric and associated with decreased urine concentrating ability and urinary magnesium wasting. With multiple daily dosing schedules, elevated aminoglycoside peak levels appear to correlate with nephrotoxicity. Because aminoglycoside uptake by proximal tubular cells is a saturable process, once-daily dosing can decrease tubular cell toxicity by reducing drug taken up by proximal tubular cells. In the general population, extended intervals between doses maintains the target dose while decreasing the risk of nephrotoxicity compared with multiple daily dosing. However, intensive care patients have different volume of distribution and variable clearance, making it difficult to attain correct serum levels with longer intervals. As these drugs are entirely excreted by glomerular filtration, patients with compromised renal function are at increased risk for nephrotoxicity. In these patients, the administration of a large single dose can be associated with a decreased uptake and lower antimicrobial effect.¹² Therefore, for treatment of serious infections in critically ill patients, dosing with maximum concentration monitoring and minimal inhibitory concentration evaluation of the pathogen is necessary.¹²

Uric Acid Nephropathy and Tumor Lysis Syndrome

Acute uric acid nephropathy is caused by deposition of uric acid crystals in the interstitium and tubules in association with tumor lysis syndrome (TLS).

The early recognition of patients at high risk for TLS is the first step to prevention of the development of AKI. In patients with high-grade hematologic malignant neoplasms, risk factors for TLS are large tumor burden, lactate dehydrogenase levels above 1500 IU, extensive bone marrow involvement, and high tumor sensitivity to chemotherapeutic agents. In patients with low or intermediate risk of TLS, allopurinol can be used as a hypouricemic agent and should be started 2 days before chemotherapy. Aggressive hydration with isotonic saline is initiated 2 days before the chemotherapy to maintain a high urinary output, allowing the elimination of uric acid and phosphate. If urinary output decreases despite adequate fluid intake, a loop diuretic should be added, but RRT will be required if oliguria persists.¹³ The use of urine alkalinization to promote elimination of urates is not recommended as it can induce calcium phosphate deposition and therefore aggravate TLS.

In addition to the hydration, recombinant urate oxidase can reduce uric acid levels and the risk of uric acid deposition nephropathy.¹⁴ Recombinant urate oxidase should be initiated in high-risk patients or for established TLS.

SECONDARY PREVENTION

After the renal insult has occurred, secondary preventive measures should be directed to avoid further injury, to facilitate repair and recovery, and to prevent AKI complications. The timeliness of interventions is crucial to their effectiveness for

secondary prevention. Various approaches have been applied but are best appreciated in the context of specific scenarios.

Traumatic and Nontraumatic Rhabdomyolysis

In the prevention of myoglobin-induced nephropathy after crush syndrome, intravenous hydration should be initiated with isotonic saline before the crushed limb is relieved to prevent precipitation of the pigment in the tubular lumen. A solution with 2.7% sodium bicarbonate (50 mmol/l) should be given every second or third liter to maintain urinary pH above 6.5 and to prevent intratubular deposition of myoglobin and uric acid. The urine output should be maintained around 300 ml/h, which may require an infusion of up to 12 liters of fluid per day. The volume administered is generally much greater than the urinary output; the accumulation of fluid in the damaged muscles may exceed 4 liters. This protocol should be continued until clinical or biochemical evidence of myoglobinuria disappears, usually by day 3. The addition of mannitol can help decompress the post-traumatic turgid edematous muscles, thus decreasing the development of compartmental syndromes.¹⁵ If urinary flow is sustained above 20 ml/h, mannitol given at a rate of 5 g/h may be added to each liter of infusate not exceeding 1 to 2 g/kg per day.¹⁶ Hypocalcemia can occur as a consequence of calcium sequestration in muscles and, as calcium is protein bound, the increased vascular permeability. Therefore, care must be taken to avoid a NaHCO₃-induced decrease in ionized calcium (due to metabolic alkalosis), which can trigger seizures and worsen existent muscle damage. An alkaline diuresis is ineffective if the patient has established AKI, and accumulation of mannitol in this setting may actually exacerbate renal injury.

In nontraumatic rhabdomyolysis, prevention of AKI involves vigorous fluid expansion to maintain renal perfusion pressure and to dilute myoglobin and other toxins. A urine output of 200 to 300 ml/h is desirable until myoglobinuria disappears. Urine alkalization may help prevent tubular pigment cast formation; however, there is no clinical evidence that mannitol and bicarbonate are more effective than saline solution alone. Furthermore, there are potential risks to bicarbonate therapy, including precipitation of calcium phosphate and hypocalcemia.

In treating patients with rhabdomyolysis, one important consideration is when to stop aggressive fluid resuscitation. Although fluid expansion is the main therapeutic intervention to reduce the hemoglobin precipitation in the tubular lumen, the risk of fluid accumulation and compartmental expansion should always be part of the clinical judgment. Frequent assessment of renal functional parameters associated with uric acid and creatine kinase levels help the clinician decide how intense the volume expansion should be.

Hyperglycemia

After the first study showing a reduction in AKI incidence and mortality with strict control of blood glucose concentration, many studies presented conflicting results. A systematic review of intensive insulin therapy in critically ill patients found a 38% reduction in the incidence of AKI¹⁷; other negative trials showed no benefit and an increased risk of hypoglycemia. In a recent large, international, randomized trial in critically ill patients (NICE-SUGAR study), intensive glucose control increased the absolute risk of death at 90 days compared with conventional glucose control. Severe hypoglycemia was significantly more common with intensive glucose control. In a meta-analysis

including 26 trials, a total of 13,567 patients, and data from the NICE-SUGAR study, the relative risk of death with intensive insulin therapy compared with conventional therapy was 0.93. Patients in surgical intensive care units had a benefit from intensive insulin therapy (RR 0.63), whereas patients in medical intensive care units did not (RR 1.0). On the basis of these studies, it appears that intensive insulin therapy significantly increased the risk of hypoglycemia and is not associated with a benefit in mortality among critically ill patients. Whether there is a benefit in preventing or ameliorating AKI is still unclear. We recommend maintaining appropriate control of blood glucose concentration in the range of 120 to 140 mg/dl.

Pharmacologic Approaches

A variety of drugs are effective in altering the course of experimental models of acute tubular necrosis (ATN). However, only a few have consistently shown benefits in established AKI (Fig. 69.5).

Acetylcysteine

N-Acetylcysteine (NAC) is a tripeptide analogous to glutathione able to cross cellular membranes. NAC may reduce vasoconstriction and oxygen free radical generation after the administration of contrast material. Because an increased production of free radicals by the kidneys is partly responsible for their cellular damage in postischemic and nephrotoxic AKI, several clinical studies have attempted to use NAC to prevent AKI, mainly in CIN and during cardiac surgery.

In the first study, NAC at a dose of 600 mg orally twice daily the day before and the day of the procedure prevented AKI after radiocontrast dye administration.¹⁸ A large, single-center RCT¹⁹ confirmed the preventive and dose-dependent effect of NAC in CIN prevention. Several meta-analyses have concluded that NAC, compared with periprocedural hydration alone, can lower the risk of CIN in high-risk patients. NAC use is recommended on the basis of its potential benefit, low cost, and excellent side effect profile. However, NAC should never replace intravenous fluids, which have a more substantial benefit. In practice, we combine both hydration and NAC in patients at risk for CIN.

Loop Diuretics and Natriuretics

Diuretic use is often associated with deterioration in kidney function and should be stopped when feasible if AKI is attributed to prerenal causes. One meta-analysis confirmed that the use of diuretics to prevent AKI did not reduce in-hospital mortality, the risk for requiring dialysis, the number of dialysis sessions required, or the proportion of oliguric patients.²⁰ No RCTs have been performed to assess the effect of natriuretics (ANP) on the prevention of AKI.

Vasoactive Agents

“Renal-dose” dopamine (0.5 to 3 µg/kg per minute), given as a specific vasodilator to increase renal blood flow and to prevent AKI, increases urine output but does not affect AKI outcome or mortality.²¹ Dopexamine, a synthetic dopamine analogue, is a dopamine 1 and less potent dopamine 2 receptor agonist. Small studies performed in patients undergoing liver transplant surgery have not found a beneficial effect of dopexamine in preventing AKI.

No RCTs have assessed the effect of norepinephrine on prevention of AKI. In a meta-analysis, fenoldopam, a dopamine receptor 1 agonist increasing blood flow to the renal cortex and

Figure 69.5 Summary of drugs used in prevention of acute kidney injury (AKI). CIN, contrast-induced nephropathy; NA, not applicable; RCTs, randomized controlled trials.

Summary of Drugs Used in Prevention of Acute Kidney Injury			
Drugs	Level of Evidence	Results	Administration
Dopamine	RCTs	No effect on kidney function	NA
Fenoldopam	Small RCTs One meta-analysis	No effect on kidney function Beneficial effect on kidney function	Further studies required
Loop diuretics	RCTs and meta-analysis	No effect on kidney function	NA
N-Acetylcysteine	RCTs and meta-analysis	Variable beneficial effect in CIN	N-Acetylcysteine 600 to 1200 mg PO bid before and the day of administration of the contrast agent along with saline or intravenous bicarbonate
Statins	Animal models	Beneficial effect on kidney function	Further studies required
	Prospective observational in CIN	Beneficial effect on kidney function	
Calcium channel blockers	RCT in peri-transplant period	No effect on kidney function	Further studies required
Adenosine antagonists	RCTs	Controversial effect on kidney function	Further studies required
Multipotent stem cells	Animal models	Beneficial effect on kidney function	Human studies required
Erythropoietin	Animal models	Beneficial effect on kidney function	Human studies required
Small interfering RNA targeting p53	Animal models	Beneficial effect on kidney function	Human studies required

outer medulla, was shown to reduce the risk of AKI in postoperative or critically ill patients (odds ratio, 0.43).²² Intrarenal administration of fenoldopam allows the use of a substantial dose of fenoldopam mesylate while avoiding systemic adverse effects, such as hypotension. In a registry of 268 patients treated with intrarenal fenoldopam infused for at least 1 hour, the incidence of CIN was less than 1%, compared with 27% based in historic rates in that population. Although we are still waiting for additional studies to confirm these results, it may be a promising preventive measurement for patients at high risk for CIN.

Statins

Although the pathogenesis of CIN is not completely known, multiple mechanisms may be involved. Statins induce downregulation of angiotensin receptors, decrease endothelin synthesis, decrease inflammation and improve endothelial function by inhibiting nuclear factor (NF) κ B, decrease expression of endothelial adhesion molecules, increase nitric oxide (NO) bioavailability, attenuate production of reactive oxygen species, and protect against complement-mediated injury. Those mechanisms may be involved in the protective effect against CIN. A number of publications support the potential for renal protection with statin administration.²³ A prospective study evaluated the effect of statins on decreasing the incidence of CIN during

percutaneous coronary intervention. Patients receiving statins before the procedure had a significant decrease of CIN (3% versus 27%).²⁴ No benefit was observed in patients with a pre-existing creatinine clearance below 40 ml/min. However, in a retrospective cohort study evaluating patients undergoing major vascular procedures,²⁵ perioperative statin administration did not improve renal function, reduce length of stay, or reduce mortality. Currently, there is no basis to recommend the initiation of statin therapy specifically for the pericontrast period to prevent CIN. Patients who are already receiving statin therapy or need it for other indications should be maintained on statins through the contrast procedures.

Calcium Channel Blockers

Calcium antagonists have been shown to reverse the afferent arteriolar vasoconstriction induced by a variety of stimuli and also have an independent natriuretic effect.²⁶ These drugs were exhaustively evaluated in the prevention of AKI, especially in the context of transplant-associated nephropathy. Administered prophylactically, calcium blockers protected against post-transplantation delayed graft failure in some studies. However, a large multicenter RCT evaluating the effect of isradipine on renal function, incidence and severity of delayed graft function, and acute rejection after kidney transplantation did not find any

benefit.²⁷ A systematic review evaluated the benefits and harms of using calcium channel blockers (CCBs) in the peri-transplant period in patients at risk of ATN after cadaveric kidney transplantation²⁸ and did not find strong evidence for the routine use of CCBs to reduce the incidence of ATN after transplantation. Studies have shown improved long-term outcomes without any significant improvement in perioperative function. We believe the use of CCBs during renal transplant surgery may be of benefit in extended donor criteria transplants (e.g., donors older than 60 years, predonation serum creatinine level higher than 1.5 mg/dl, cerebrovascular disease as the cause of death) or those with prolonged ischemia times.

Adenosine Antagonists

Small clinical studies evaluating the role of theophylline, an adenosine antagonist, in the prevention of contrast nephropathy have shown discordant results. A meta-analysis including seven RCTs concluded that the prophylactic administration of theophylline or aminophylline appeared to protect against CIN.²⁹ However, this meta-analysis included studies that did not control for hydration status. A recent RCT adding theophylline to NAC showed reduced incidence of CIN. Additional selective blockers agents, such as rolofylline, have maintained renal function in patients with decompensated heart failure, although they have not been assessed for prevention of AKI. At the current moment, it remains unclear if theophylline as a solo agent might be useful in preventing CIN. Newer agents may be promising.

Emerging Agents

Multipotent mesenchymal stem cells were shown to prevent ischemia-reperfusion-induced AKI in rats. A phase 1 clinical trial is currently being performed in patients at high risk for AKI undergoing open heart surgery. In mice, erythropoietin (EPO) administered 30 minutes before the infusion of endotoxin significantly improved kidney function 16 hours after injury. EPO also seems to have a protective effect against ischemia-reperfusion injury in the rat kidney. There are ongoing RCTs looking at the effect of EPO or placebo on prevention of AKI in patients undergoing heart surgery or kidney transplantation. In the intensive care setting a recent study failed to show therapeutic renoprotective benefits of EPO. Although the timing to receive treatment was not ideal, more than 6 hours, this study using high-dose erythropoietin did not alter outcome in AKI patients.³⁰ Another RCT comparing the effect of EPO or placebo on prevention of AKI in patients receiving intravenous contrast material has just ended, but results are not currently available. In an animal model of AKI, those treated with small interfering ribonucleic acid targeting p53 presented a significant decrease in BUN and creatinine levels 24 hours after ischemic injury compared with animals treated with a placebo. Small interfering ribonucleic acids are currently being evaluated against placebo for prevention of AKI in a phase 1 clinical trial. Because p53 has, among other activities, a tumor suppression function, one of the major drawbacks to the use of an inhibitor of p53 is its potential carcinogenic effect.

TREATMENT OF ACUTE KIDNEY INJURY

Once measures to prevent AKI have failed, a key question is whether AKI can be managed with nondialytic therapy alone or if RRT is necessary (see Chapter 70). Management of AKI in the setting of cardiac failure and liver failure is discussed in Chapters 71 and 72, respectively.

General Management

Initial management of established AKI includes careful assessment of the etiology of renal dysfunction and the patient's volume status. The main goal includes maintenance of adequate hemodynamic status to ensure renal perfusion and avoidance of further kidney injury. Appropriate therapeutic interventions to reduce kidney function loss and for prevention and treatment of the associated complications of AKI need to be instituted concurrently. Any potentially nephrotoxic agents should be avoided, including intravascular radiocontrast dye. Antimicrobial agents such as aminoglycosides, amphotericin, acyclovir, and pentamidine should be avoided or their dose adjusted to prevent further insult. Any other medications associated with AKI (hemodynamic, nephrotoxic, immune mediated) should also be avoided if possible.

Fluid and Electrolyte Management

Whereas early and vigorous resuscitation with crystalloid solutions and aggressive infection control can reduce the incidence of AKI (see earlier discussion), the role of fluid resuscitation in established AKI is less clear. Volume status is one of the most difficult parameters to assess, and fluid resuscitation should target a predefined preload, stroke volume, or cardiac output rather than a set MAP. Nevertheless, many clinical studies have emphasized the poor value of right atrial pressure and pulmonary artery occlusion pressure in predicting volume expansion efficacy. Other bedside indicators of preload, such as the right ventricular end-diastolic volume (evaluated by thermodilution) and the left ventricular end-diastolic area (measured by echocardiography), have also been shown to be ineffective in differentiating volume responder from nonresponder patients.³¹

In critically ill patients receiving mechanical ventilation, respiratory changes in left ventricular stroke volume can predict fluid responsiveness. In hypovolemic patients, positive-pressure ventilation may induce a fall in the venous return and consequently in cardiac output. Based on the positive relationship between ventricular end-diastolic volume and stroke volume, the expected hemodynamic response to volume expansion is an increase in right ventricular end-diastolic volume, left ventricular end-diastolic volume, stroke volume, and cardiac output. Because a decrease in ventricular contractility decreases the slope of the relationship between end-diastolic volume and stroke volume, the increase in stroke volume as a result of end-diastolic volume increase depends on ventricular function.

Volume expansion in critically ill patients can frequently result in a relative increase in body weight of 10% to 15% or more, sometimes doubling the total body water in a short time. Some studies have demonstrated an association between fluid accumulation and mortality and the benefits of restrictive fluid management strategies in acute respiratory distress syndrome. A prospective multicenter observational study (PICARD) found that patients with fluid overload, defined as an increase in body weight relative to baseline of more than 10%, had significantly higher mortality at 60 days (46% versus 32%).⁶ In addition, increases in the total body water alter the volume of distribution of creatinine, resulting in underestimation of serum values. The resulting underestimation of the severity of renal dysfunction may delay recognition and adequate treatment of AKI. In AKI patients presenting with fluid overload, the evaluation of renal function should consider the effect of fluid balance to prevent underestimation of AKI severity, to modify drug dosing correctly, and to avoid use of nephrotoxic agents.

Figure 69.6 Summary of drugs used in treatment of acute kidney injury (AKI). NA, not applicable; RCTs, randomized controlled trials.

Summary of Drugs Used in Treatment of Acute Kidney Injury			
Drug	Level of Evidence	Results	Comment
Loop diuretics	RCTs and meta-analyses	No effect	Further studies required; use for short periods of time if needed
Atrial natriuretic peptide	RCTs	Possible beneficial effect on survival and kidney function	Further studies required
Dopamine	RCTs	No effect on mortality or kidney function	
Norepinephrine	Prospective observational studies	Possible beneficial effect on kidney function	Further studies required
Fenoldopam	RCTs	No effect on mortality or kidney function	Further larger studies required
	One meta-analysis	Beneficial effect on mortality and need for dialysis	
Insulin	Meta-analyses	Controversial effect	NA
Mesenchymal stem cells	Animal models	Beneficial effect on kidney function	Further studies required
Erythropoietin	Animal models	Beneficial effect on kidney function	Further studies required
Alkaline phosphatase	Small RCT	Beneficial effect on kidney function	Further studies required

Drugs to Promote Recovery from Acute Kidney Injury

See Fig. 69.6 for a summary of drugs used in treatment of acute kidney injury.

Loop Diuretic Therapy

Although loop diuretics are often prescribed in established AKI,³² a meta-analysis confirmed that their use is not associated with reduced mortality or better kidney recovery.³³ However, in this meta-analysis, there was an association between diuretic use and a shorter duration of dialysis (mean 1.4 days). Two other meta-analyses have shown that loop diuretics do not affect mortality, need for dialysis, or number of dialysis sessions required.^{20,34} Two prospective cohort studies evaluating diuretic use in AKI and mortality yielded controversial results; one study showed an increase,³⁵ and the other study showed no effect.³⁶ In regard to morbidity, diuretics are associated with an increased risk of ototoxicity.²⁰ Concomitant prescription of aminoglycosides and diuretics should be avoided because of an increased risk of ototoxicity. Well-designed trials of diuretics are required to assess their benefits and potential side effects in AKI. In the meantime, we suggest that a trial of diuretics may be used to enhance urine output; however, if it is not successful, escalating doses of diuretics should be avoided.

Natriuretics

Atrial natriuretic peptide (ANP) has been studied as a treatment of AKI in four RCTs.³⁷⁻⁴⁰ ANP was shown to reduce need for

dialysis but not mortality.³⁷ In the largest study published so far, ANP improved overall dialysis-free survival in the subgroup of oliguric patients only.³⁸ Unfortunately, a subsequent trial including 222 oliguric patients did not confirm that ANP reduces mortality or dialysis-free survival.⁴⁰ Both trials delivered ANP for 24 hours and at high doses, which could have influenced the results. The most recent study included 61 patients who underwent cardiac surgery and were treated with ANP for a mean of 5.3 ± 0.8 days. In this small study, the use of ANP decreased the probability of dialysis and improved dialysis-free survival.³⁹ Larger studies are required to confirm the benefits of ANP in AKI.

Nesiritide, a B-type natriuretic peptide, is currently approved by the Food and Drug Administration for the treatment of heart failure. Nesiritide induces vasodilation and an indirect increase in cardiac output but has no inotropic effects and neutral effect on heart rate. In addition, it inhibits adverse neurohormonal activation and can result in natriuresis and diuresis in some individuals. In adults with acute decompensated heart failure, nesiritide reduces pulmonary capillary wedge pressure, right atrial pressure, and systemic vascular resistance; decreases symptoms of heart failure; and enhances clinical status. However, questions about the risks of nesiritide therapy have been raised. The most frequently reported adverse effect is dose-related hypotension and an acute increase in serum creatinine concentration. This effect on renal function has not been shown to negatively affect mortality, and reviews of large, observational registry databases do not suggest an adverse inpatient mortality effect compared with other vasodilator therapies.

Vasoactive Agents

As in the case of prevention, dopamine use for the treatment of established AKI is no longer recommended (see earlier discussion).

Vasopressors are often considered to be detrimental for organ perfusion. In septic shock, a small prospective study including 14 patients showed that norepinephrine improved serum creatinine and creatinine clearance when MAP was raised above 70 mm Hg.⁴¹ However, in a small RCT including 28 patients, increasing MAP from 65 to 85 mm Hg with norepinephrine did not improve renal function.⁴²

In a meta-analysis, fenoldopam decreased the need for dialysis (7% versus 10%) and in-hospital mortality (15% versus 19%) in postoperative or critically ill patients.²² Several limitations were present in this meta-analysis, such as no standardized criteria for initiation of dialysis, heterogeneity of populations and AKI definitions, dosage and duration of treatments, and absence of an independent measure of GFR. In addition, fenoldopam has hypotensive properties and may be more dangerous in the “real world” outside of RCTs.^{22,43} No single prospective study has shown that fenoldopam can reduce the need for dialysis. Therefore, before the use of fenoldopam is widely promoted, these results need to be confirmed with an adequately powered trial.

Specific therapy for patients presenting with the hepatorenal syndrome includes the use of terlipressin in combination with octreotide (see Chapter 72). In the United States, terlipressin has not been available, and most centers use a combination of midodrine, octreotide, and albumin infusions. Norepinephrine has also been used in these settings with good response, equivalent to terlipressin (see Chapter 72).

Other Agents

Other agents have been studied to treat established AKI. Mesenchymal stem cells were used to treat AKI in rats suffering from ischemia-reperfusion-induced AKI. In this study, the administration of mesenchymal stem cells significantly reduced creatinine levels on days 2 and 3. Human clinical trials are required to confirm these findings. EPO might also be beneficial in the treatment of AKI, as shown in two animal models. However, in a retrospective study including 187 patients with AKI, the use of EPO was not associated with renal recovery. In severe sepsis and septic shock, a study including 36 patients has shown that the infusion of alkaline phosphatase improves kidney function, possibly through reduced NO metabolite production and attenuated tubular enzymuria.⁴⁴

Treatment of Acute Kidney Injury Complications

Fluid Overload

When fluid overload occurs in a patient with AKI, all intakes should be minimized and medical treatment should be attempted before dialysis initiation. In patients with positive fluid balance with large fluid intakes and inadequate urine output and in those presenting with symptomatic volume overload, loop diuretic therapy can be initiated in conjunction with measures to optimize systemic and renal perfusion. Intravenous bolus doses of diuretics may be necessary to optimize the response, especially in patients with CHF and nephrotic syndrome, but there is no other benefit from continuous infusions over bolus therapy.

Although administration of loop diuretics facilitates fluid management in critically ill patients with AKI, concerns of possible harm from loop diuretics in AKI arose after studies associated diuretic use with an increased adjusted risk of death and

nonrecovery of renal function. A systematic review of furosemide including nine randomized studies of furosemide found no significant effect on in-hospital mortality, risk for requiring RRT, or number of dialysis sessions. Nevertheless, high-dose furosemide (1 to 3.4 g daily) was associated with an increased risk of temporary deafness and tinnitus.

In addition to diuretics, new drugs that selectively influence the excretion of water or sodium have been developed and can be used in specific clinical settings. Aquaretics act in the collecting duct of the kidney in the vasopressin 2 receptors, contributing to free water excretion. Natriuretic peptides inhibit sodium reabsorption in the nephron, resulting in net sodium excretion. There is currently no evidence to support the use of natriuretic peptides as an adjunctive treatment in AKI. Nesiritide (brain natriuretic peptide, BNP) is the latest natriuretic peptide introduced for clinical use, only for the therapy of acute decompensated heart failure, and data suggest that kidney function deteriorates under therapy with nesiritide (see earlier discussion). Vasopressin receptor antagonists are an alternative for volume management of patients with heart failure; further studies are under way to establish their role in the treatment of AKI with volume overload and hyponatremia.

Morphine and nitrates can be used to alleviate the respiratory symptoms in urgent situations. Morphine reduces the patient's anxiety and decreases the work of breathing; it can be administered intravenously at an initial dose of 2 to 4 mg during a 3-minute period and can be repeated if necessary at 5- to 15-minute intervals. Nitrates are the most commonly used vasodilators in pulmonary edema. Nitroglycerin reduces left ventricular filling pressure through venodilation; an initial dose of 5 µg/min of intravenous nitroglycerin can be used, commonly in addition to diuretic therapy. When fluid overload cannot be quickly treated with medical management, positive-pressure ventilation may need to be initiated with or without endotracheal intubation and dialysis, depending on the clinical situation (see Chapter 70).

Potassium Disorders

Hyperkalemia, covered in detail in Chapter 9, is a frequent complication of AKI. Its primary risk is on cardiac conduction, and it may cause bradycardia or asystole. If electrocardiographic changes are present, the intravenous administration of calcium is urgent. Concomitantly, sources of oral or intravenous potassium should be identified and removed, including drugs with effect on potassium handling, such as β -adrenergic antagonists, potassium-sparing diuretics, ACE inhibitors, ARBs, and other drugs that inhibit renal potassium excretion.

The next step is to enhance the shift of potassium to the intracellular space by parenteral glucose and insulin infusions. The onset of action is within 20 to 30 minutes, and their effect lasts 2 to 6 hours. Continuous infusions of insulin and glucose-containing intravenous fluids can be used to prolong their effect. Sodium bicarbonate also promotes shift of K^+ into the intracellular space; the effect occurs in less than 15 minutes and has 1 to 2 hours of duration. This therapy can be started if there is no concern of fluid overload (44.6 mEq intravenously during 5 minutes), although the potassium-lowering effect of sodium bicarbonate is most prominent in patients with metabolic acidosis. β -Adrenergic agonists given as aerosols are effective but more likely to produce side effects and therefore not often prescribed to treat hyperkalemia.

Potassium excretion should be increased by the administration of saline, loop diuretics, and cation exchange resins such as

Kayexalate or calcium resins. The resins can be administered orally or rectally as a retention enema. In case of hyperkalemic emergencies, rectal administration is preferred, as the colon is the major site of action of this drug. If hyperkalemia is unresponsive to conservative measures or occurs in patients with end-stage renal disease (ESRD), emergency hemodialysis (HD) is the treatment of choice. Continuous renal replacement therapy (CRRT) techniques can also be used for hyperkalemia with higher volumes of replacement solution or dialysate with low or no potassium levels. As it may take some time to initiate RRT, medical management should always be used while waiting for dialysis to be initiated. Monitoring of potassium levels should continue after conservative or dialytic management to prevent and to treat rebound hyperkalemia from the underlying process.

Sodium Disorders

Hyponatremia is not common in AKI unless heart failure, liver failure, or diuretics are present. In these settings, water restriction to below the level of output is mandatory. Sodium restriction is usually necessary to treat fluid overload and edema. In cases of true volume depletion with associated prerenal AKI, isotonic saline will need to be administered to correct both disorders (see Chapters 7 and 8).

Intensive care patients with hyponatremia are more prone to AKI. In most cases, treatment of the underlying cause will be necessary and water deficit will need to be estimated. Water should be administered orally or intravenously as dextrose in water to correct serum sodium concentration at a maximum rate of 10 mmol/l per day. Dialysis and CRRT in particular may be required to optimally correct sodium disorders in AKI.

Calcium, Phosphorus, and Magnesium Disorders

Hyperphosphatemia and hypocalcemia are common in AKI. Hyperphosphatemia is usually due to a reduced excretion by the kidneys, although it can also be caused by a continuous release from rhabdomyolysis or TLS (see Chapters 66 and 68). As phosphorus levels increase, calcium levels decrease, resulting in hypocalcemia. The levels of reduction are usually mild to moderate, with total calcium levels dropping to 7 to 8 mg/dl (1.75 to 2.0 mmol/l). Other causes of hypocalcemia in AKI are skeletal resistance to parathyroid hormone (PTH) and low calcitriol production from the dysfunctional kidney. Hypocalcemia can also occur during rhabdomyolysis and pancreatitis, two conditions often associated with AKI. Hypocalcemia is also aggravated when bicarbonate is administered to correct acidosis. A high calcium-phosphorus product ($>60 \text{ mg}^2/\text{dl}^2$; $>4.64 \text{ mmol}^2/\text{l}^2$) could theoretically trigger tissue calcium deposition, which can cause cardiac arrhythmia. No randomized study has evaluated the benefits of treating these disorders. However, because hyperphosphatemia due to oral phosphorus-containing medications and TLS can cause AKI,⁴⁵ severe hyperphosphatemia should be avoided to prevent further damage. Calcium-base phosphate binders and other phosphate binders can be used in this setting.⁴⁶ If there are symptoms of hypocalcemia or hemodynamic instability, a calcium gluconate infusion should be administered.

Hypercalcemia is rare in AKI and is usually seen in the recovery phase of rhabdomyolysis when calcium is released from calcium-containing complexes in muscle (see Chapters 66 and 68). In addition, when production of calcitriol is reestablished by the recovering kidney, an enhanced responsiveness to PTH can be seen. Hypercalcemia in this setting is rarely problematic and can be easily treated with medical management. Mild

hypermagnesemia is frequent in AKI and usually does not have clinical consequences.

Acid-Base Disorders

In AKI, metabolic acidosis is the most common acid-base abnormality (see Chapter 12) and is due to reduced regeneration of bicarbonate and failure to excrete ammonium ions. Accumulation of phosphate and unexcreted unmeasured anions, such as sulfate, urate, hippurate, hydroxypropionate, furanpropionate, and oxalate, is contributory. Hypoalbuminemia can attenuate this acidification process, and it is exacerbated by lactic acidosis. Despite retention of unmeasured anions, the anion gap remains within normal limits in 50% of patients. Whereas metabolic acidosis is frequent, triple acid-base disturbances can also occur.

The approach to acid-base disturbances in AKI needs to be adjusted to the underlying causes.

There is controversy surrounding the optimal treatment of acute metabolic acidosis. When metabolic acidosis is simply a complication of AKI, sodium bicarbonate can be administered if the serum bicarbonate concentrations fall below 15 to 18 mmol/l. Volume overload can occur after the administration of bicarbonate. Bicarbonate administration in lactic acidosis due to an underlying shock is controversial given the possibility of an increase in carbon dioxide generation, worsening of the intracellular acidosis, and volume overload. Rapid improvement in the metabolic status may also enhance hypocalcemia, which may lower cardiac output. Therefore, because the benefit of bicarbonate in patients with lactic acidosis due to an underlying shock seems limited, most physicians would restrict the administration of sodium bicarbonate to patients with severe metabolic acidosis (arterial pH below 7.10 to 7.15) to maintain the pH above 7.15 to 7.20 until the primary process can be reversed. Alternative forms of base treatment have not been studied extensively in patients with AKI. Tris(hydroxymethyl)aminomethane (THAM) is excreted in the urine, and its clinical efficacy compared with sodium bicarbonate remains unproven.⁴⁷ We do not recommend its use in patients with AKI, especially in patients with hyperkalemia, because THAM does not decrease potassium levels in contrast to bicarbonate and can even cause hyperkalemia. Restriction of protein intake has also been suggested as a method of acidosis control because protein breakdown has been associated with worsening acidosis, such as in CKD.⁴⁸ However, no studies have clearly demonstrated the benefit of protein restriction on acid-base status in AKI.

Nutritional Considerations

AKI patients have an increased risk of protein-energy malnutrition due to poor nutrient intakes and high catabolic rates. Nutritional support should be directed to ensure adequate nutrition, to prevent protein-energy wasting with its concomitant metabolic complications, to promote wound healing and tissue repair, to support immune system function, to accelerate recovery, and to reduce mortality.

Nutritional assessment is difficult, especially in AKI patients presenting higher metabolic demands. Subjective global assessment evaluates nutritional status, requires no additional laboratory testing, and is highly predictive of outcome.⁴⁹

Patients with AKI should receive a basic intake of at least 1.5 g/kg per day of protein and an energy intake of no more than 30 kcal nonprotein calories or 1.3 times the basal energy expenditure, calculated by the Harris-Benedict equation. Thirty

percent to 35% of calories should come from lipid, as lipid emulsions.

Monitoring of nitrogen balance to assess the effectiveness of supplemental nutritional therapy is determined by measuring protein intake during 12 or 24 hours and urinary excretion of urea nitrogen during the same time interval. A positive or negative protein balance is used to determine the adequacy of protein intake of the patient. It is calculated as follows:

$$\text{Nitrogen balance} = (\text{protein intake}/6.25) - (\text{UUN} + 4)$$

Protein intake and urinary urea nitrogen (UUN) are each expressed in grams.

The enteral route should be the first choice for nutritional support if the gastrointestinal tract is functioning; parenteral nutrition should be reserved for when the gastrointestinal tract cannot be used or when the enteral route appears inadequate to reach nutrient intake goals.⁵⁰ AKI itself and other factors commonly present in critically ill patients, such as medications, hyperglycemia, and electrolyte disorders, can impair gastrointestinal motility.

Dialytic Management of Acute Kidney Injury and Intensive Care Unit Nephrology

Mark R. Marshall

Intensive care unit nephrology can be defined as a subspecialty that focuses on abnormalities of fluid, electrolyte, and pH homeostasis in intensive care unit (ICU) patients and the prevention and management of acute kidney injury (AKI).

By use of the RIFLE (risk, injury, failure, loss, and end stage) criteria (see Fig. 68.1), up to 65% of ICU patients have evidence of AKI, an independent risk factor for death. The nondialytic therapy for AKI is discussed in Chapter 69. Approximately 5% of ICU patients receive acute renal replacement therapy (ARRT). Mortality in this population appears to be gradually improving over time despite a higher degree of illness severity, although it remains high in absolute terms.¹ Death attributable to AKI appears to be due to nonresolving infection, hemorrhage, or nonresolving shock, despite optimal care. Such conditions may therefore comprise an acute uremic syndrome that is specific to AKI and a possible target for modulation with ARRT as opposed to the traditional uremic syndrome of end-stage renal disease (ESRD).

ORGANIZATIONAL ASPECTS OF ACUTE RENAL REPLACEMENT THERAPY PROGRAMS

ICUs can be referred to as open (patient care remains under the attending physician of record), closed (patient care is transferred to an intensivist), or co-managed (an open ICU in which patients receive mandatory consultation from an intensivist). Most ICUs in the United States are open, whereas most in Australia and New Zealand are closed. Those in Europe are approximately equally split. In considering AKI and ARRT, advantages of intensivist-based management include immediate availability of service, cost containment, and decreased fragmentation of care. This model of care is supported by ecological studies suggesting improved patient outcomes in health care systems with closed ICUs, although these studies often lack internal validity because of important residual confounding. Alternatively, advantages of nephrology-based management include greater understanding of dialysis dosing and membrane design and of the processes underlying AKI and their implications. This model of care is supported by studies showing improved outcomes in ICU patients with AKI associated with earlier consultation to nephrology, although these studies often lack external validity in health care systems with closed ICUs where expertise is “in-house.” Clinical governance over ARRT is therefore likely to remain a point of contention between intensivists and nephrologists in the future, although the individual expertise of staff providing care probably influences patient outcomes more than the specialty to which

they belong. Specific training in ICU nephrology with exposure to ARRT is inadequate in many critical care and nephrology training fellowships, and it should be a component of both core curriculums.

In many parts of the world, all modalities of ARRT are now delivered by ICU nursing staff; in other countries, support from nephrology staff is still sought. As machinery platforms are becoming universal for continuous renal replacement therapy and intermittent hemodialysis, it is likely that ICU expertise in all modalities of renal replacement therapy will grow, provided in-service education and support are sufficient to develop and to maintain the skill base.

OVERVIEW OF ACUTE RENAL REPLACEMENT THERAPIES

The four main modalities of ARRT are acute intermittent hemodialysis (iHD); continuous renal replacement therapy (CRRT); prolonged intermittent renal replacement therapy (PIRRT), otherwise known as sustained low-efficiency dialysis (SLED); and acute peritoneal dialysis. Globally, CRRT is the most popular modality, although practice patterns vary regionally because of cost, availability of technology, and reimbursement policies. PIRRT is becoming more popular, and for reasons of cost and convenience, it may become the dominant ARRT in the future. Acute peritoneal dialysis is only occasionally used in adults and is not considered further in this chapter.

Therapeutic goals for ARRT are not well defined. The usual minimum recommendation is to correct acidosis or hyperkalemia, refractory hypervolemia, and traditional uremic features such as pericarditis and coma. Serum electrolyte and bicarbonate concentrations should be maintained in the normal range. Targets for uremic solute control are discussed later in this chapter. Importantly, the process of ARRT itself should not jeopardize the patient by exacerbating hemodynamic instability, increasing end-organ damage, or delaying renal recovery.

Determination of therapeutic goals with respect to the patient's fluid status is not straightforward. Assessment itself is difficult; physical signs such as jugular venous distention are not often informative, especially for mechanically ventilated patients. Moreover, baseline values of central venous pressure, pulmonary capillary wedge pressure, and echocardiographic left ventricular diastolic dimensions may be inaccurate surrogates for intravascular volume status, especially for septic patients. More reliable approaches use the effect of therapeutic maneuvers such as fluid challenge on blood pressure, stroke volume, or vena cava

collapsibility obtained by bedside echocardiography. Even once fluid status is adequately assessed, determination of the therapeutic goal is also difficult; patients with extracellular fluid excess in the absence of intravascular hypervolemia may benefit from fluid removal if they develop abdominal compartment syndrome, impairment of lung compliance and oxygenation, or poor wound healing. Patients with acute respiratory distress syndrome (ARDS, defined as low P_{aO_2} relative to inspired oxygen, diffuse pulmonary infiltrates, and no left atrial hypertension) require a shorter period of ventilation with less fluid loading (guided by central filling pressures). However, the benefit of fluid removal in ARDS by means of ARRT has not been established.

Increasingly, ARRT is being used to facilitate adsorption or clearance of unconventional uremic markers and mediators such as proinflammatory cytokines, which might contribute to the purported acute uremic syndrome by their cardiodepressant, vasodilatory, and immunomodulatory properties. Because ARRT will remove both proinflammatory and anti-inflammatory cytokines, there is the potential to inadvertently exacerbate the inflammatory milieu.² The evolving technique of high-volume hemofiltration (HVHF) in septic shock is an area of intense study, supported by observations in septic ICU patients with AKI of improved outcomes with higher doses of hemofiltration (≥ 45 ml/kg per hour) and improved hemodynamic stability with HVHF (60 to 100 ml/kg per hour) applied either as a “pulse” or continuous maneuver. Presently, there are insufficient outcome data to justify routine clinical use of HVHF. Clinical trials of this approach, such as the IVOIRE (hIgh Volume in Intensive Care) study, are under way.³

Timing of ARRT initiation remains controversial and current practices vary widely. A large multinational cohort study showed that ARRT was initiated when the median (IQR) serum creatinine and urea levels were 309 (202 to 442) $\mu\text{mol/l}$ and 24 (15 to 35) $\mu\text{mol/l}$, respectively, and when urine output was 576 (192 to 1272) ml/day.⁴ Observational studies suggest that earlier rather than later initiation might achieve better outcomes, and none suggests that it is harmful. There is no high-quality evidence to guide practice, and the single clinical trial designed to answer the question was insufficiently powered.⁵ Proponents of early initiation argue that it is in the patient's interest to prevent rather than to treat the acute uremic syndrome and recommend initiation to prevent or to minimize fluid overload and biochemical abnormalities once kidney injury or failure is present. Timing of ARRT initiation is currently the leading priority for research in AKI.⁶

An important determinant of modality choice is cost. More complex extracorporeal circuits and replacement fluids make CRRT generally more expensive than iHD or PIRRT. Pharmacoeconomic studies comparing ARRT modalities are all limited by wide variation in ICU cost and reimbursement structures.

ACUTE INTERMITTENT HEMODIALYSIS

Acute intermittent hemodialysis (iHD) is still a widely used modality for the management of AKI when the patient has sufficient hemodynamic stability. Hemodialysis techniques and adequacy are discussed in the context of maintenance treatment of ESRD in Chapters 89 and 90.

Techniques for Acute Intermittent Hemodialysis

Acute iHD is categorized according to hemodialyzer membrane and mechanism of solute removal. High-flux membranes allow

greater convective removal of middle and larger solutes, but there are only limited clinical data on high-flux dialysis in the critically ill with AKI, and these do not show obvious advantages.⁷ Biocompatibility defines a membrane with a low capacity for activating complement and leukocytes. After complement activation, there is stasis of leukocytes in the lungs, renal parenchyma, and other organs, and the release of products of leukocyte activation. By minimizing these processes, use of biocompatible membranes should in principle favorably affect mortality and recovery of renal function in ICU patients with AKI. Unfortunately, studies to resolve this issue have often been confounded by poor design, and meta-analyses have not clarified this issue. A reasonable recommendation can be made against the use of less biocompatible unsubstituted cuprophane membranes.

Hemodiafiltration (HDF) is usually performed in the ICU as a continuous modality. However, acute intermittent HDF can be performed in this setting with standard machinery, using sterile online replacement fluid generated from ultrapure dialysate, which is then diverted by a separate pump to be infused directly into the extracorporeal blood circuit. As with high-flux dialysis, limited clinical data do not show obvious advantages.

Dialysate for the single-pass machines is generated online with a proportioning system from concentrate using reverse osmosis-treated tap water. There is concern about the possibility of backfiltration of bacterial contaminants, specifically endotoxin, which could perpetuate microcirculatory insult and cytokine-mediated injury. As a minimum, dialysate for iHD should be of the same purity as that accepted for ESRD settings. Online replacement fluid for intermittent HDF is produced by cold sterilization using ultrafilters in the dialysate pathway fluid and does not differ from commercial hemofiltration (HF) solutions in terms of microbial counts, endotoxin concentration, and cytokine-inducing activity. Dialysate cold sterilization is also suggested by some for acute iHD, although there are insufficient data to support a strong recommendation.

Strategies to Reduce Intradialytic Hemodynamic Instability

Hypotension is detrimental for end-organ function and recovery. Fresh ischemic lesions in kidney biopsy specimens can be found in patients with RIFLE failure stage of more than 3 weeks in duration. The relatively high ultrafiltration rate (UFR) with iHD often leads to intradialytic hypotension, which reduces residual renal function. A frequent schedule of iHD and prolonged treatment time will minimize ultrafiltration goals and rates and is the most effective measure to minimize hypotension.

Bicarbonate-buffered dialysate should be used routinely in critically ill AKI patients. It is associated with less hypotension than acetate dialysate, which has a peripheral vasodilating and myocardial depressant effect.

The rapid reduction in serum osmolality with iHD promotes water movement into cells, thus reducing effective circulating volume. Sodium profiling mitigates this process by promoting water flux into the vascular compartment, although the simpler approach of a high-sodium dialysate without profiling also may achieve this and needs to be tested in the ICU setting. A randomized study showed that iHD with sodium profiling (160 mmol/l initially, reducing to 140 mmol/l) combined with ultrafiltration profiling (50% of ultrafiltration volume removed in first third of treatment) improved hemodynamic stability.⁸ Profiling therefore seems to be safe and effective, although it should be used judiciously in the patients with dysnatremias, in which serum sodium

concentrations should be corrected slowly to minimize the risk of neurologic complications (see Chapter 7).

Relative blood volume monitoring with a biofeedback system automatically adjusts UFR and dialysate sodium content in response to a decrease in circulating blood volume. Although it is effective for ESRD patients, relative blood volume monitoring does not correlate with volumetric and hemodynamic parameters measured with transpulmonary thermodilution and does not appear useful for preventing hypotension in ICU patients.⁹

High dialysate calcium (1.75 mmol/l) has been used to improve hemodynamic stability during iHD in ESRD patients with cardiomyopathy. This technique is limited by the development of hypercalcemia, however, and has not been studied in ICU patients with AKI.

Vasoconstriction due to lower body temperatures has been used to increase vascular resistance and to improve hemodynamic stability during iHD in ESRD. Hypothermia, however, may be undesirable in ICU patients because of adverse effects on myocardial function, end-organ perfusion, blood clotting, and probably renal recovery. With blood temperature monitoring, the patient's blood temperature is precisely maintained at target value by a series of feedback loops controlling thermal transfer to and from the dialysate. Blood temperature monitoring is effective in ameliorating hemodynamic instability for ESRD patients. Blood temperature monitoring might conceivably allow controlled cooling in ICU patients without the risk of hypothermic damage, but it has not been evaluated in this setting.

In the ESRD setting, hemodynamic stability may be better during intermittent HDF compared with conventional iHD, although prospective controlled studies are contradictory. This could theoretically be related to heat loss in the circuit, lower sodium removal, higher calcium flux, and enhanced removal of endogenous vasoactive substances leading to increased peripheral vasoconstriction. There are insufficient data in ICU patients with AKI to support a strong recommendation.

Measures to reduce hemodynamic instability during iHD are summarized in Figure 70.1.¹⁰ Should these measures fail, modality change to PIRRT or CRRT is recommended.

Dosing of Acute Intermittent Hemodialysis

The relationship between acute iHD dose and mortality has been clarified in several studies. A retrospective observational study

showed that delivered single-pool Kt/V ($spKt/V$; see Chapter 90) above 1.0 per treatment was associated with improved survival in patients with intermediate illness severity.¹¹ This study did not relate outcomes to frequency of treatments. A prospective, controlled trial demonstrated that delivered $spKt/V$ of 0.9 to 1.0 per treatment six or seven times per week improved survival compared with this dose three or four times per week. In this study, the time-averaged blood urea nitrogen (BUN) in the lower dose group (104 mg/dl) indicates underdialysis by current standards.¹² Most recently, a prospective, randomized controlled trial showed that delivered $spKt/V$ of 1.2 to 1.4 per treatment five or six times per week did not improve survival compared with this dose thrice weekly.¹³

Optimal iHD dose therefore appears to be related to small rather than to larger solute clearance, and there appears to be a dose above which survival becomes dose independent. This “breakpoint” in the iHD dose-response curve suggests a recommended iHD dose: delivered $spKt/V$ of 1.2 or more per treatment at least thrice weekly. This mandates routine measurement of $spKt/V$ for iHD treatments in ICU patients with AKI to guide appropriate adjustment of operating parameters. Delivered dose tends to be low in this population and is optimized by measures summarized in Figure 70.2.¹⁰ If delivered $spKt/V$ of 1.2 or more per treatment cannot be achieved, dose should be maintained as high as possible and treatment frequency increased. The required number of treatments per week and dosing interval can be established from the nomogram in Figure 70.3 expressing combinations of iHD dose and treatment frequency as a continuous small-solute clearance (expressed as the corrected equivalent

Measures to Improve Hemodynamic Stability During Intermittent HD
Minimize ultrafiltration rate requirements by Increased frequency of treatments (up to daily) Increased duration of treatments (up to 6 hours), then consider PIRRT (SLED) or CRRT
Bicarbonate-buffered dialysate
Sodium/ultrafiltration profiling
? Increase dialysate $[Ca^{2+}]$
? Change modality from hemodialysis to hemodiafiltration
? Blood temperature monitoring

Figure 70.1 Measures to improve hemodynamic stability during intermittent HD. CRRT, continuous renal replacement therapy; PIRRT, prolonged intermittent renal replacement therapy; SLED, sustained low-efficiency dialysis. (Modified from reference 10.)

Measures to Increase Intermittent Hemodialysis Dose
Maximize hemodialyzer surface area (up to 2–2.2 m ²)
Maximize hemodialyzer porosity (high flux)
Maximize blood flow rate by Maximizing internal lumen diameter of catheter (up to 2.0–2.2 mm) Titration blood flow to maximum arterial and venous pressure (up to – and + 300–350 mm Hg, respectively) Correcting position of catheter tip in SVC and IVC as appropriate Use right-sided IJ and SC in preference to left-sided IJ and SC
Minimize access recirculation by correcting position of catheter tip in superior or inferior vena cava as appropriate using internal jugular and subclavian, rather than femoral, catheters
Maximize dialysate flow (up to 800–1000 ml/min)
Add postdilution HDF
Optimize anticoagulation to reduce hemodialyzer fiber bundle clotting
Optimize circulation to reduce compartmental urea sequestration
Increased treatment frequency (up to daily)
Increased treatment duration (up to 6–8 hours, then consider PIRRT (SLED) or CRRT)

renal urea clearance), aiming for a value of 12.6 ml/min or more.¹⁴

CONTINUOUS RENAL REPLACEMENT THERAPY

CRRT involves the application of lower UFR and solute clearances for substantial periods every day. Solute removal is achieved by diffusion, convection, or a combination. CRRT is used to complement or to supplant iHD. The lower UFR provides comparatively better hemodynamic stability than with iHD, especially during ultrafiltration of large obligatory fluid loads, and the lower solute clearances result in single-pool solute kinetics despite discrepancies in regional blood flow due to pressor use. The longer treatment duration results in better and more consistent control of uremic solutes, especially for severely catabolic patients.

Interruptions to CRRT because of circuit clotting or out-of-unit procedures lead to a reduction in dose from downtime as well as expense related to blood circuitry changes. Mean operating time for CRRT has been reported at 21.9 h/day.¹⁵

Techniques of Continuous Renal Replacement Therapy

The Acute Dialysis Quality Initiative group (www.adqi.net) has proposed standardized classification, with nomenclature based on the type of vascular access and the method of solute removal.

Arteriovenous (AV) denotes an extracorporeal blood circuit in which an arterial catheter allows blood to circulate by systemic blood pressure. A venous catheter is placed for return. AV circuits are simple but involve arterial puncture, which can lead to distal embolization, hemorrhage, and vessel damage. A blood flow (Q_b) of 90 to 150 ml/min is typical in patients with mean arterial pressure above 80 mm Hg, although flow can be erratic, predisposing to clotting. Venovenous (VV) denotes a circuit with a central venous catheter, achieving more reliable and rapid Q_b

of ~250 ml/min by a mechanical pump. Pumped VV circuits have the disadvantage of potential inadvertent disconnection of lines, resulting in hemorrhage or air embolism with continued pump operation; this risk is minimized but not eliminated by monitors and alarms.

Mechanisms of Solute Removal

Hemodialysis

Continuous hemodialysis (HD) provides diffusive small-solute transport that can be quantified according to the degree to which dialysate is saturated with urea (expressed as the ratio of dialysate to blood urea nitrogen or DUN/BUN). Q_b and dialysate flow (Q_d) during CRRT are usually relatively low (100 to 200 ml/min and 1 to 2 l/h, respectively). Under these conditions, the dialysate to blood urea nitrogen ratio (DUN/BUN) is 1.0, indicating complete saturation. Urea clearance therefore equals Q_d and is unaffected by Q_b until it decreases to less than 50 ml/min.

With increasing Q_d , there are proportionally decreasing gains in small-solute clearance as the DUN/BUN progressively decreases. Figure 70.4 illustrates this principle.¹⁶ The flattening of the curves describes the conditions in which increasing Q_b does not enhance clearance. At Q_b of 200 ml/min, urea clearance will correspond to Q_d at a rate of 2 l/h (or less) and will not increase with increased Q_b . If Q_d is increased to 4 l/h, this will correspond to a urea clearance of ~3 l/h that will progressively increase with increased Q_b .

Hemofiltration

Continuous HF provides convective transport of small and medium-sized solutes that can be similarly quantified by use of filtrate saturation with urea (FUN/BUN). An important determinant of clearance is the site of fluid replacement, which can be infused either into the arterial blood line leading to the hemofilter (predilution) or into the venous blood line leaving the hemofilter (postdilution). The standard method is postdilution.

However, higher UFR can lead to hemoconcentration in the hemofilter, increased resistance in the blood flow pathway, reductions in Q_b , and ultimately hemofilter clotting. In practice, UFR should not exceed 30% of the plasma water flow rate (i.e., filtration fraction should be <0.30). The problem can be resolved by increasing Q_b to ≥ 200 to 250 ml/min or by diluting the blood and clotting factors with replacement fluid before it reaches the hemofilter (predilution), thereby improving filter patency and decreasing anticoagulant requirements.

Figure 70.4 Determinants of urea clearance during continuous hemodialysis. Relationship between urea clearance, Q_b (blood flow), and Q_d (dialysate flow) during continuous hemodialysis. The flattening of the urea clearance curves describes the conditions in which increases in Q_b do not enhance clearance. (From reference 16.)

The disadvantage of predilution is that filtrate is generated from blood diluted with replacement fluid and therefore contains a lower concentration of uremic solutes. Small-solute clearance is reduced by $\sim 15\%$ at low UFR, although this figure increases to $\sim 40\%$ with a higher UFR.^{17,18} Clearance of any given solute during continuous HF is

$$K (\text{postdilution}) = \text{UFR} \times S$$

$$K (\text{predilution}) = \text{UFR} \times S \times [Q_{bw} / (Q_{bw} + Q_r)]$$

where K is clearance (ml/min), S is the sieving coefficient of the solute, Q_{bw} is blood water flow rate equal to the product of Q_b and $(1 - \text{hematocrit})$, and Q_r is the replacement fluid rate.

Hemodiafiltration

Continuous HDF refers to a combination of the preceding techniques. With large enough membranes, the small-solute clearances obtained approach the sum of the individual techniques.¹⁷

Specific Techniques

CRRT techniques are shown in Figures 70.5 and 70.6. The choice of technique is dependent on equipment availability, clinician expertise, prospects for vascular access, and whether the primary need is for fluid or solute removal. This last factor is often the most important because each technique provides different rates of fluid and solute removal. Most clinicians avoid AV circuits because of higher vascular complication rates. The potential complications of the techniques are listed in Figure 70.7.¹⁹

For isolated fluid removal, slow continuous ultrafiltration (SCUF) can be used. Given its minimal solute clearance (equal to the UFR at generally 4 to 5 ml/min), SCUF has primarily proved useful for treatment of the cardiorenal syndrome (see Chapter 71).

Most ICU patients require removal of solute in addition to that of fluid. For this, most clinicians prefer pumped VV rather than AV circuits because of higher and more reliable Q_b , allowing greater solute clearance. The substantially enhanced clearance capabilities of continuous HDF combine diffusion and convection for removal of both small and medium-sized solutes

Comparison of Continuous Renal Replacement Modalities						
Modality	Blood Pump	Dialysate (D) Replacement Fluid (RF)	Urea Clearance (l/day)	Urea Clearance (ml/min)	Middle Molecular Clearance	Complexity
Slow continuous ultrafiltration	Yes/no	No	1–4	1–3	+	+

and can be applied to hypercatabolic and intoxicated patients. The benefit of larger solute clearance is uncertain in this population, whereas the benefits of small-solute clearance are more evident (see later discussion). The long cherished practice of treating lactic acidosis with CRRT should be discarded. Extracorporeal lactate clearance is between 10- and 100-fold lower than plasma clearance, and the only effective treatment of lactic

acidosis is improving tissue oxygenation to prevent acid production.

Dosing of Continuous Renal Replacement Therapy

The relationship between CRRT dose and mortality has been established in several prospective, randomized controlled trials. The first demonstrated that an effluent volume flow rate above 35 ml/kg per hour (based on pre-morbid or pre-ICU weight) of postdilution continuous HF was associated with highest survival. The external validity of this study, however, is limited by the small patient size and the predominantly postsurgical causes of AKI.²² Another demonstrated that the addition of 18 ml/kg per hour of continuous HD to ~25 ml/kg per hour of predilution continuous HF resulted in improved survival.²³ Most recently, two more trials demonstrated that more than 35 ml/kg per hour of predilution continuous HDF did not improve survival compared with 20 ml/kg per hour, and another demonstrated that 40 ml/kg per hour of postdilution continuous HDF did not improve survival compared with 20 ml/kg per hour.^{13,24,25}

Optimal CRRT dose therefore appears to be related to small as much as to larger solute clearance, and as with iHD, there appears to be a dose above which survival becomes dose independent. This breakpoint in the CRRT dose-response curve varies by study but suggests a minimum recommendation for CRRT dose: an effluent volume flow rate of 20 ml/kg per hour. As for iHD, this mandates routine measurement of dose on a regular basis.

Technical Aspects of Continuous Renal Replacement Therapy

Equipment

VV CRRT requires a blood pump, a hemofilter or hemodialyzer, arterial and venous pressure monitors, an air detection system, a method for removal of air bubbles, and a system to balance dialysate inflow/replacement fluid with dialysate outflow/filtrate. Integrated machinery dedicated to CRRT is commercially available with computerized volumetric or gravimetric balancing, allowing accurate and reliable treatment delivery.

Hemofilters

Specific devices for CRRT are usually referred to as hemofilters. However, conventional inexpensive hemodialyzers can serve as hemofilters by occlusion of one of the dialysate ports and connection of the other to a drainage system. To achieve adequate UFR, the surface area must be large ($\sim 2 \text{ m}^2$) for low-flux or, alternatively, more modest ($\sim 0.5 \text{ m}^2$) for high-flux hemodialyzers. Some CRRT machines use a specific hemofilter because of a unique cartridge system. Sieving coefficients of small solutes are usually preserved throughout the life of all such hemofilters.

A promising innovation has been the recent use of so-called superflux hemofilters with a cutoff of 100 to 150 kd. When they are used with CRRT and iHD *ex vivo* or in healthy volunteers, significant convective removal of cytokines can be achieved, and studies are under way to determine effects on clinical outcomes. Albumin losses may prevent prolonged use of such filters.

Replacement Fluids and Dialysate

CRRT requires sterile replacement fluid or dialysate for blood purification, with composition that is determined by the clinical requirements for acid-base control and electrolyte management. Fluids are available commercially or can be prepared aseptically

in hospital pharmacies. A commonly used regimen consists of a blended mixture of 1 liter of each of four different solutions, which are kept separate until allowed to mix through a multi-prong adapter just before entering the blood pathway:

1. Isotonic saline (0.9% NaCl) plus 7.5 ml 10% calcium chloride (5.2 mmol calcium).
2. Isotonic saline plus 1.6 ml 50% magnesium sulfate (3.2 mmol magnesium).
3. Half-isotonic saline.
4. Half-isotonic saline plus 150 mmol sodium bicarbonate.

Options for replacement fluids are summarized in Figure 70.8.

Buffer choice is between bicarbonate and lactate, which metabolizes in the liver to bicarbonate in a 1:1 ratio. Although many patients tolerate lactate solutions, bicarbonate solutions are superior in terms of acid-base control, hemodynamic stability, urea generation, cerebral dysfunction, and possibly survival in patients with a history of cardiovascular disease. Overall, bicarbonate has become the buffer of choice and is preferred in patients with lactic acidosis or liver failure. If lactate-buffered fluids are used, the development of lactate intolerance ($>5 \text{ mmol/l}$ increase in serum lactate during CRRT) may require a switch to bicarbonate-based fluid. Bicarbonate concentrations in fluid are typically 25 to 35 mmol/l; concentrations in the lower part of this range are indicated during high-dose or prolonged CRRT and during regional citrate anticoagulation therapy to prevent metabolic alkalosis.

Glucose concentrations in fluids range from 0.1% in commercially prepared fluids to 1.5% to 4.25% in peritoneal dialysis fluids adapted for use with CRRT. Up to 3600 kcal/day may be derived from these latter solutions, although hyperglycemia may supervene to the detriment of patient outcomes. It is recommended that glucose intake be less than 5 g/kg per day and that glucose concentration in fluid be ~ 100 to 180 mg/dl (~ 5.5 to 10 mmol/l) to maintain zero glucose balance.

Replacement Fluids for CRRT							
Component (mmol/l)	Dialysis Machine Generated*	Peritoneal Dialysis Fluid†	Lactated Ringer's Solution	Accusol [‡] (2.5-liter bag)	Prismasate (5-liter bag)	NxStage [§] (5-liter bag)	Normocarb [¶]

Braun Medical Inc.

Intravenous phosphate supplementation is often required during CRRT and is usually administered separately because of the potential for precipitation with calcium and magnesium in dialysate or replacement fluid. This concern may have been overstated in the past, and phosphate has been safely supplemented by injection of phosphate into these solutions.

PROLONGED INTERMITTENT RENAL REPLACEMENT THERAPY

PIRRT should replace alternative names such as sustained low efficiency dialysis (SLED), slow low efficiency dialysis, go slow dialysis, extended dialysis, extended daily dialysis, accelerated venovenous filtration. PIRRT uses standard iHD equipment and accessories, but with lower solute clearances and UFR maintained for prolonged periods.²⁷ Typical operating parameters would be Q_b of 200 to 300 mL/min and Q_d of 300 mL/min for regimens of 8 hours or less, and Q_b of 100 to 200 mL/min and Q_d of 100 to 200 mL/min for regimens longer than 8 hours. The systems are fully monitored with computerized ultrafiltration control. Q_d and urea clearances are higher than in conventional CRRT, which allows scheduled downtime without compromise in dialysis dose.

PIRRT provides a high dose of dialysis with minimal urea disequilibrium, online bicarbonate dialysate, excellent control of electrolytes, and good tolerance to ultrafiltration. PIRRT is usually delivered as a diffusive therapy (a subgroup of PIRRT referred to as extended dialysis), although there is increasing experience with combined diffusive and convective clearance using online replacement fluid (extended diafiltration). Survival in the reported observational series has not differed from that predicted by a variety of illness severity scores. ARRT that is easiest to administer will be the most popular if all such outcomes are equivalent, and PIRRT may become the therapy of choice in this setting as it is safe, convenient, inexpensive, and effective in achieving goals for solute and fluid removal.

VASCULAR ACCESS

A prerequisite for all ARRT modalities is reliable vascular access. This is usually through uncuffed, untunneled (temporary) double-lumen polyurethane or silicone catheters in the internal jugular (IJ), subclavian (SC), or femoral (FE) veins. SC catheters are associated with a higher incidence of procedural complications, venous stenosis, and thrombosis.

For CRRT and PIRRT, Q_b below 250 mL/min is usually sufficient. For acute iHD, higher Q_b is required to provide sufficient solute clearance, and it can be safely increased until venous and arterial pressures are plus and minus 350 mm Hg, respectively, after which hemolysis can occur. Left-sided IJ and SC catheters provide flows that are more erratic and up to 100 mL/min lower than elsewhere because their tips abut the vein walls. FE and right-sided IJ or SC catheters provide the best Q_b .²⁵ Catheters with larger bore lines are preferred.

Access recirculation for all sites is approximately 10% at Q_b of 250 to 350 mL/min and may increase to as much as 35% at Q_b above 500 mL/min. It is least in IJ catheters and highest in FE catheters shorter than 20 cm. Up to half of acute iHD treatments will require catheters to be used in reversed configuration, such that the original venous line is used as for blood inflow (relative to dialyzer), and the original arterial line for outflow. Access recirculation in this situation doubles to ~20% at 250 to 350 mL/min.

Access recirculation also affects dialysis dose; in one study, the urea reduction ratio was significantly higher with SC (63%) versus FE (55%) catheters despite identical iHD operating parameters.²⁹

Infection of temporary catheters is common. Blood stream, exit site, and distant infections occurred in one series at 6.2, 3.6, and 1.1 episodes per 1000 catheter-days.²⁸ The risk of bacteremia is highest with FE catheters and lowest with SC catheters. Although there are generally fewer data than for tunneled catheters, both povidone and mupirocin ointments with dry gauze exit site dressings and antimicrobial locks using taurolidine or 30% trisodium citrate have been shown to reduce the risk of blood stream infection from temporary catheters.

The Centers for Disease Control and Prevention recommend that temporary catheters in the ICU setting be changed when it is clinically indicated rather than routinely because the risks of the catheterization outweigh the supposed benefit of reduced infection risk.³⁰ KDOQI (Kidney Disease Outcomes Quality Initiative) recommends that SC and IJ catheters be changed after 3 weeks and FE catheters after 5 days in the non-ICU setting because of increased infection risk.³¹

ANTICOAGULATION IN ACUTE RENAL REPLACEMENT THERAPY

Anticoagulation during ARRT ideally should prevent clotting in the extracorporeal circuit without producing significant systemic anticoagulation. Most commonly, unfractionated heparin is infused into the most proximal part of the extracorporeal circuit, keeping the activated partial thromboplastin time in the venous blood line 1.5 to 2 times the control value and the systemic activated partial thromboplastin time below 50 seconds. This typically requires an initial bolus dose of ~2000 U and maintenance infusion of ~500 U/h. Low-molecular-weight heparin is theoretically advantageous because of increased antithrombotic activity and decreased hemorrhagic risk. However, disadvantages include a prolonged half-life (approximately doubled in RIFLE failure stage), incomplete reversal with protamine, and limited availability of appropriate monitoring by serial anti-factor Xa determinations. Most experience is with dalteparin, and the optimal dose appears to be an initial bolus of ~20 to 30 U/kg (all ARRT modalities), followed by an infusion of ~10 U/kg per hour (CRRT and PIRRT). Other systemic anticoagulants include lepirudin (recombinant hirudin, notable for its very long half-life in those with reduced renal function) and argatroban, which are direct thrombin inhibitors, and fondaparinux, which is a synthetic pentasaccharide that inhibits factor Xa by binding to anti-thrombin. Experience with these anticoagulants is limited, although they are the anticoagulants of choice in patients with heparin-induced thrombocytopenia who also require ARRT.

For those receiving systemic anticoagulation with heparin, the incidence of significant bleeding complications is 25% to 30%, and 4% of such patients die as a result of hemorrhage. Most patients can successfully avoid any anticoagulation during iHD, but only a minority can during PIRRT or CRRT. Alternatives to systemic anticoagulation include regional citrate anticoagulation, regional heparin anticoagulation, and prostacyclin (epoprostenol), which is a potent inhibitor of platelet aggregation that essentially acts as a regional anticoagulant. The lowest rates of hemorrhage and greatest prolongation of filter life are associated with regional citrate anticoagulation, and it is the preferred regional technique.

Regional citrate anticoagulation involves calcium chelation in the extracorporeal blood circuit with calcium reversal. For iHD and PIRRT, this most commonly involves an infusion of 4% trisodium citrate into the proximal circuit, with zero calcium dialysate and an infusion of calcium chloride into the venous blood line. A simpler approach has been described in which the trisodium citrate infusion is combined with normal calcium dialysate and no calcium infusion. The positive calcium flux through the hemodialyzer maintains calcium balance without the need for a separate infusion and provides partial chelation of the undialyzed citrate.

For CRRT, regional citrate anticoagulation may be performed with 4% trisodium citrate or with ACD-A solution (anticoagulant citrate dextrose A). ACD-A is preferred to trisodium citrate as it is less hypertonic, potentially reducing complications from overinfusion and mixing errors. For continuous HD, a prefilter infusion of 3% to 7% of Q_b with a postfilter infusion of calcium chloride is used. This requires dialysate that is hyponatremic and devoid of alkali because citrate metabolizes to bicarbonate in the liver in a 1:3 ratio. For continuous HF, a prefilter infusion of substitution fluid that contains no calcium but citrate as buffer can be used (Fig. 70.9). Frequent monitoring and titration of citrate dose are needed to keep the ionized calcium within a therapeutic range. The major complications of regional citrate anticoagulation are systemic hypocalcemia and metabolic alkalosis from citrate toxicity, particularly in patients with liver dysfunction.

Regional heparin anticoagulation involves neutralization of heparin by infusion of protamine into the venous blood line. It

may be complicated by rebound bleeding, occurring when neutralization with protamine wears out faster than the anticoagulation from heparin. Furthermore, protamine may cause sudden hypotension, bradycardia, or anaphylactoid reactions.

Prostacyclin is an effective alternative anticoagulant. However, it is a vasodilator, causing a variable but occasionally marked decrease in blood pressure.

MODALITY CHOICE AND OUTCOMES IN ACUTE RENAL REPLACEMENT THERAPY

The prime advantage of CRRT appears to be the increased hemodynamic stability and solute control; patient survival does not appear to differ between AV and VV CRRT when dose is the same. Observational reports have previously suggested improved survival with CRRT compared with iHD, but numerous confounding variables have made definitive comparison with iHD difficult. Small randomized clinical trials and subsequent meta-analyses comparing iHD and CRRT have shown no difference in patient survival.³²

The relationship between modality choice and outcomes is currently under study in specific clinical situations, such as acute lung injury, sepsis, and acute cardiac decompensation. Such studies may yet yield definitive data, but in the interim, modality choice depends on the patient's condition and the clinical objectives. In most cases, iHD can provide safe and effective renal replacement therapy, with recourse to other therapies as the individual situation dictates. For example, CRRT will be more

Comparison of Regional Citrate Anticoagulation Protocols					
	Modality	Blood Flow (ml/min)	Replacement Fluid Composition (mmol/l)	Dialysis Fluid Composition (mmol/l)	Citrate Source

Figure 70.9 Comparison of regional citrate anticoagulation protocols. ACD-A, anticoagulant citrate dextrose form A; CAV-HD, continuous arteriovenous hemodialysis; CVV-HD, continuous venovenous hemodialysis; CVV-HDF, continuous venovenous hemodiafiltration; PD, peritoneal dialysis.

appropriate for a patient unable to achieve ultrafiltration goals with iHD because of hemodynamic instability, and HVHF may be more appropriate than iHD for a highly catabolic septic patient.

Ultimately, the skill and experience of the staff providing renal replacement therapy probably influence patient outcomes as much as the choice of modality does.

DRUG DOSING IN ACUTE RENAL REPLACEMENT THERAPY

For patients undergoing CRRT, 20 liters of daily filtrate correspond to a glomerular filtration rate of ~14 ml/min, and the dose of drugs should be calculated accordingly. Any drug with a low therapeutic index that can be readily measured should be measured frequently early in the course of ARRT, until a stable pattern appears. One day of CRRT is in general comparable to one iHD treatment with regard to drug removal.

Ultrafiltration Therapy for Refractory Heart Failure

Edward A. Ross, Claudio Ronco

Nephrologists are being increasingly consulted for fluid management in patients with refractory congestive heart failure (CHF), a condition in part due to poorly controlled hypertension and the growing prevalence of obesity and the metabolic syndrome. Renal expertise extends beyond diuretics and electrolyte homeostasis and now includes recent advances in extracorporeal fluid removal by dialysis machines or isolated ultrafiltration modalities. In this chapter, we review the treatment options for severe CHF and develop clinical recommendations from the perspective of the cardiorenal syndrome.

DEFINITION AND SCOPE OF THE PROBLEM

CHF and renal dysfunction may coexist, but each disease can also cause or exacerbate the other. Poor cardiac output may result in kidney ischemia and progressive chronic kidney disease (CKD). Conversely, CKD may result in salt and water retention, hypertension, activation of the renin-angiotensin-aldosterone system (RAS), and vascular calcification that causes cardiac dysfunction, accelerated atherosclerosis, and left ventricular hypertrophy and remodeling.

In the Acute Decompensated Heart Failure National Registry (ADHERE), an analysis of more than 100,000 patients with CHF, 57% had stage 3 or stage 4 CKD, 7% were at stage 5 (68% receiving dialysis), and only 9% had normal kidney function. In subjects with CHF who presented with CKD at the time of admission, there was greater use of diuretics and inotropes, less angiotensin-converting enzyme (ACE) inhibitor and angiotensin receptor blocker (ARB) administration, and 5% higher in-hospital mortality.¹

The cardiorenal syndrome has undergone a classification into several categories (Fig. 71.1),² including cardiorenal (heart causing kidney disease), renocardiac (CKD leading to CHF), and syndromes with both being primary disorders or secondary to systemic conditions.

PATHOGENESIS

In cardiorenal syndrome, low cardiac output worsens renal perfusion and function, activating the RAS and other systems, leading to salt and water retention (see also Chapter 7), then a paradoxical worsening of cardiac function. Central to this vicious circle is tubuloglomerular feedback (described in Chapter 2), which is maladaptive in heart failure and in the case of some drugs that alter tubular sodium delivery. Secondary aldosteronism (resulting in increased sodium retention), increased systemic vascular resistance (thereby putting more strain on the heart),
